In the estimation of ammonia in water and for work upon conductivity of dilute solutions, the volatile impurities are much the more serious. Fortunately simple precautions suffice to eliminate them. Organic matter may be destroyed by adding to the raw water in the still a small proportion of potassium permanganate or manganate, with sufficient caustic soda or potash to make the water distinctly alkaline (Stas, *Mém. Acad. Belg.* 1865, 35, 1; *Chem. News*, 1861, 4, 207; 1867, 15, 204). Practically the whole of the carbon dioxide and ammonia will come over with the first 20–30 p.c. of the distillate, and if this be rejected the remaining two-thirds will be pure water.

Many procedures have been described, in which the acidic and basic impurities are retained in the still by added reagents, e.g. aluminium sulphate, potassium hydrogen sulphate or phosphoric acid to retain ammonia, or lime or baryta to retain carbon dioxide (see, e.g. Hulett, *Zeitsch. physikal. Chem.* 1896, 21, 297; Walker and Cormack, *J. Chem. Soc.* 1902, 77, 5; W. R. Bousfield, *ibid.* 1905, 87, 740; 1912, 101, 1443). Some workers have obtained fair conductivity distilled water by redistillation of laboratory distilled water without added reagents (see Bousfield, *l.c.*; Hartley, Campbell and Poole, *J. Chem. Soc.* 1906, 83, 428; Thole, *ibid.* 1912, 101, 207).

In a simpler method for the positive chemical elimination of basic and acidic impurities in one operation, a large glass flask containing an aqueous solution of 10 p.c. potassium dichromate and 5 p.c. sulphuric acid is heated, raw water is run in at a rate equal to the rate of evaporation, and the steam is led through a second flask, also heated, containing saturated baryta solution and then condensed in tin (Moseley and Myer, *J. Amer. Chem. Soc.* 1918, 40, 1409: this method was partially employed by Paul, *Zeitsch. Elektrochem.* 1914, 20, 179).

But still simpler methods are effective. It has long been known that ordinary 'conductivity' water, having a conductivity about 1.0×10^{-6} mho (1 gemmho) is materially improved by contact with an atmosphere freed from carbon dioxide, e.g. by enclosure over lime or even by passing through it clean air from the open, whilst it deteriorates markedly in contact with air contaminated by human breath or by flames (Kohlrausch, *Zeit. physikal. Chem.* 1902, 42, 193).

If a current of purified air be passed through such water heated nearly to its boiling-point in a quartz still, and the water distilling under these conditions be condensed in block tin and collected in quartz, it has a conductivity of $0.05-0.07 \times 10^{-6}$ mho at 18° (Weiland, *J. Amer. Chem. Soc.* 1918, 40, 131). Such water compares favourably with the purest conductivity water prepared by distilling repeatedly *in vacuo* in sealed glass vessels and had a conductivity of 0.043×10^{-6} mhos at 18° (Kohlrausch and Heydweiller, *Zeitsch. physikal. Chem.* 1894, 14, 317; Kohlrausch, *Proc. Roy. Soc.* 1903, 71, 338). This method is applicable only to those cases where carbon dioxide is the sole impurity, but the same principles have been applied in a method, applicable to all types of water, first described by Bourdillon (*J. Chem. Soc.* 1913, 103, 791) and elaborated by Clevenger (*J. Ind. Eng. Chem.* 1919, 11, 964). Raw water containing potassium bisulphate or phosphoric acid is distilled, and the steam is carefully scrubbed and separated from spray and led into a long vertical tube through which a current of purified air passes from the bottom upward. The upper end of this tube is surrounded by a water-jacket maintained nearly at 100°, which, therefore, condenses, but does not cool, the major portion of the steam; the uncondensed steam escapes either to the air or to a second condenser. The hot condensate which flows down the walls of the tube in contact with pure air, is cooled by a cold-water jacket surrounding the lower part of the tube and passes away by a syphon. The apparatus is best constructed wholly of copper heavily tinned and soldered with pure tin. Thus it is not difficult to prepare water having a conductivity about 0.05×10^{-6} mho, but it cannot be preserved save under rigid exclusion of atmospheric carbon dioxide. In contact with clean air its conductivity increases to a limiting value of about 0.75×10^{-6} mho, which is that of a solution of carbonic acid in equilibrium with the $0.035 (\pm 0.004)$ volume p.c. of carbon dioxide present in air (Kendall, *J. Amer. Chem. Soc.* 1916, 38, 1480). Kendall has suggested that as such a solution is permanent it is preferable to use it and correct for its

known conductivity rather than to use water of lower conductivity, the correction for which must be uncertain (Kendall, J. Amer. Chem. Soc. 1916, 38, 2460; *q.v.* also for a full discussion and bibliography of previous work on the preparation of conductivity water).

Pure water has been prepared in other ways. Baker found that pure water prepared by the union of pure and dry hydrogen and oxygen differs in some respects from ordinary pure water. If steam from pure water be passed through a red-hot silica tube and then condensed in silica and Jena glass, the condensate acts upon pure 1 p.c. sodium amalgam much more slowly than do other types of water. This inactivity is independent of the conductivity of the water, and there is evidence that it is due to the absence from such water of traces of hydrogen peroxide which constitute a normal impurity in ordinary pure water (Baker and Parker, J. Chem. Soc. 1913, 103, 2060; Parker, *ibid.* 2071).

Pure water may also be prepared by dehydrating pure hydrates, *e.g.* hydrated barium chloride or telluric acid, H_2TeO_6 , by heat; but the method has usually been applied to obtain very small, accurately known, amounts of water in closed apparatus, and little or nothing is known of the properties of such water.

THE RELATION OF PRESSURE AND TEMPERATURE FOR STEAM, WATER, AND ICE.

The pressure, temperature, volume, and state of aggregation of water are, of course, interdependent, and it is thus difficult to discuss separately the effect of variation of any one or two of these factors. Possibly the simplest method is to discuss first the relations of pressure and temperature for the various states of aggregation, and then consider the effect upon volume of varying temperature and pressure considered separately.

Fig. 1 is the complete pressure-temperature diagram for water, except that to save space the steam-line ΔJ is not continued to the critical point at which it terminates, viz. $374^\circ C.$ and 217 atm. The diagram is defective also in that the line ALM stands for the vapour-pressure curves of both ice and supercooled water, which are in fact distinct but by an amount entirely inappreciable on the scale of pressure necessarily adopted. The line AL represents the vapour pressure of supercooled water, which has been measured down to -16.3° and is given in Table 1; the line AM shows the vapour pressure of ice which has been measured down to about -70° , and is given in Table 2 from -80° to 0° . The maximum difference between the vapour pressures of ice and supercooled water is 0.200 mm. at -11.7° .

The vapour pressure of water has been the subject of much accurate experimental work. The data given in Table 3 from 0° – 100° and in Table 4 from 100° – 370° , and represented on the diagram by the line ΔJ , are the values regarded as most probable.

The area below the line MJ represents the vapour phase, and water as we know it at or near atmospheric pressure, is, on the scale of Fig. 1, represented by little more than the thickness of that line.

For many purposes the changes in the boiling-point of water attending small changes of pressure are of great practical importance. At pressures in the neighbourhood of 1 atm. the value of dt/dp for $dp=1$ mm. of mercury is 0.0376° (Wiebe, *Zeitsch. für Instrumentkunde*, 1893, 13, 329); and the precise values of the boiling-point of water at pressures from 720–800 mm. of mercury are given in a form convenient for reference in Table 5.

Our knowledge of the rest of the PT diagram, covering a range of temperature from -80° to $+80^\circ$ at pressures from 1 to over 20,000 $kgm./cm.^2$, rests upon the work of Tammann as confirmed and extended by Bridgman. The principal numerical data are given in Tables 6 and 7, which show respectively the variations in the melting-points and transition-points of the various forms of ice with variation in pressure; their significance is evident from a consideration of Fig. 1. The line AB represents the equilibrium between water and ordinary ice, Ice I. At pressures above about 2000 $kgm./cm.^2$, whatever the temperature, Ice I cannot exist, but changes into one of the denser forms of ice, II or III, the equilibria between which and Ice I are represented respectively by $K'GB$ and KGB . The line $K'G$ represents stable equilibrium between Ice I and Ice II, whereas KG is the locus of equilibrium between Ice I and Ice III in a metastable condition. Ice III has a stable existence only in the range of temperature and pressure denoted by the area $BCFG$, within which are smaller areas (shown on a larger scale in the upper part of Fig. 1) in which labile modifications of Ice I and Ice III, called respectively Ice I' and Ice III', can exist. The inter-relation of these forms is not as yet well understood.

Two other still denser forms of ice exist at higher pressures. Ice V is in equilibrium with Ice III at about 3500 $kgm./cm.^2$ over a small range of temperature in the neighbourhood of -20° ; its equilibrium with Ice II has been followed over a small range only, the point x being conjectural. The stable equilibrium between Ice V and water, indicated by the line cn , has been traced some distance into the area of Ice III as shown, Ice V being here metastable. Above a pressure of about 6500–8000 $kgm./cm.^2$ Ice V and Ice II are converted into Ice VI, the only form observed at higher pressures. Its equilibrium with liquid water is represented by the line pn , and it is remarkable that at the highest pressures this form is stable at temperatures up to 75° . The existence of metastable Ice VI in equilibrium with liquid water has been traced along the line dp' for a considerable distance in the area of Ice V. The estimated densities of the different forms of ice are:—Ice II 1.03; Ice III 1.04; Ice V 1.06; Ice VI 1.09; as compared with ordinary ice 0.92 and water=1.00.

It must be understood that the evidence for the separate existence of these solids is simply the abrupt change of volume, manifested by a sudden drop of pressure, observed in a mass of water subject to isothermal compression. The conclusion that these are solid forms of water is supported by the fact that Ice III formed at about 2500 $kgm./cm.^2$ and -20° to -30° , if cooled first to -80° and then

WATER.

to -190° , is so stabilised that it is unchanged on release of pressure and can be examined in the open. At temperatures of -120° or higher under atmospheric pressure, the clear trans-

parent Ice III breaks down into a bulky powder of Ice I (Tammann, *Zeitsch. anorg. Chem.* 1909, 63, 285; *Zeitsch. physikal. Chem.* 1910, 72, 609; 1913, 84, 257).

FIG. 1.

The extent and direction of the line DN are of great theoretical interest, inasmuch as they lend no support to the hypotheses which have been formulated (Poynting, *Phil. Mag.* 1881, [5], 12, 32; Ostwald, *Lehrbuch der allgemeinen Chemie*, 1902, 2, ii. 373, 391; Tammann, *Kristallisieren und Schmelzen*, Leipzig, 1903, 29; Planck, *Wied. Ann.* 1882, 15, 446) that the melting-point curve of a solid should, with increase of pressure, terminate at a critical end-point analogous to that of the boiling-point curve, or pass through a maximum.

Critical data for water have been determined as follows:

Authority	Crit. temp.	Crit. press.	Crit. vol.	Crit. density
1	358.1°	—	0.001874	0.429
2	364.3°	194.6 atm.	0.003864	—
3	374.0°	217.0 atm.	—	—

TABLE 3.

VAPOUR PRESSURE OF WATER FROM 0° TO 100°.

In millimetres of mercury at 0°C. at sea-level in latitude 45°. Temperatures on the constant volume gas-thermometer (Reichsanstalt) scale.

(Landolt-Börnstein: *Physikalische-Chemische Tabellen.*)

THE RELATION OF VOLUME AND TEMPERATURE
AT MODERATE PRESSURES FOR STEAM,
WATER, AND ICE.

It is convenient next to consider the relation
of the volume of unit mass of water to tem-

perature at ordinary or moderate pressures,
and the available data are presented in a further
series of tables. Table 8 shows the specific
volume in c.c. per gram of saturated water
vapour corresponding to each degree of temper-
ature from 0°-180°; the specific volume of

TABLE 8.
SPECIFIC VOLUME OF SATURATED WATER VAPOUR.

In cubic centimetres per gram, at temperatures on the constant volume gas-thermometer
(Reichsanstalt) scale.

180	195.1	—	—	—	—	—	—	—	—	—

Calculated by Holborn, Scheel and Henning (Wärmetabellen, 1919) from the results of Holborn and Henning (Ann. Physik. 1906, [iv.] 28, 833) and Henning (ibid. 1906, [iv.] 31, 649; 1909, [iv.] 39, 441). See also J. Southern, Phil. Mag. 1903, 17, 120.

superheated steam is similarly given at 10° intervals of temperature and for pressures from 1-19 kgm./cm.² in Table 9.

The specific volume is given for super-cooled water from -13° to 0° in Table 10, and for stable water from 0°-35° by tenths of a

degree in Table 12, from 30°-100° by degrees in Table 14, and, under pressure of the saturated vapour for ten-degree intervals, from 100°-320° in Table 15. For convenience, the same data in terms of specific gravity are given also in Tables 10, 11, 13 and 15.

9. Vincent, Proc. Roy. Soc., 1902, 69, 422.

A large number of formulæ, for the most part entirely empirical, have been proposed to express the variation of volume of water with temperature, and these are collected, e.g. in Landolt-Börnstein Tabellen, 1921, p. 1231.

As examples the following may be given for water from 0°–40° and from 17°–100° respectively, due to Thiesen, Scheel and Dieselhorst (Wiss. Abh. Phys.-Tech. Reichsanstalt, 1900, 3, 1), and Thiesen (Wiss. Abh. Phys.-Tech. Reichsanstalt, 1903, 4, 1). If s = the density,

$$1 - s = \frac{(t - 3.98)^2}{503570} \times \frac{t + 283}{t + 67.26} \quad (\text{from } 0^\circ - 40^\circ)$$

$$1 - s = \frac{(t - 3.982)^2}{466700} \times \frac{t + 273}{t + 67} \times \frac{350 - t}{365 - t} \quad (\text{from } 17^\circ - 100^\circ)$$

These volume changes may also be considered in terms of the coefficient of cubical expansion α ,

which varies with temperature in the general manner indicated below:

Temp.	20°	40°	60°	100°	140°	180°	200°
$\alpha \times 10^6$	110	217	305	452	584	722	788

(See Meyer, Nernst's Festschrift, Halle a. S., 1912, 278; Hirn, Ann. Chim. 1866, [iv.] 10, 32; Tammann and Zepernik, Zeitsch. physikal. Chem. 1895, 16, 659.)

Despite many investigations our knowledge of the density and expansion of ice is not entirely satisfactory. Table 16 gives an indication of the methods adopted, the kinds of ice used, and the final results obtained in the chief researches on the subject; the papers by Barnes and Cooke and by Vincent, cited in the Table, contain critical reviews of earlier work and should be consulted for more detailed information.

Upon examination it is at once apparent

that these data differ among themselves by amounts much greater than any experimental error to which the actual determination of density can conceivably be subject.

With isolated exceptions the values for natural ice approximate to 0.918, whilst those for artificial ice are near 0.916. The mean values in the Table are respectively less than and greater than these figures, because they each include exceptional data which appear from their magnitude to belong to the other classification. Nichols first drew attention to this apparently systematic difference, and his experiments seem to show firstly, that it is real, and secondly, that the density of natural ice decreases with lapse of time until it approaches that of artificial ice. The experiments of Barnes and Cooke, made with natural ice from the St. Lawrence river, which had been in storage for various periods up to three years, confirm the correctness of the lower value for old natural ice, but it seems probable that none of their samples of ice were as recently formed as those which other observers had found of high density, and their conclusion that age has no effect on the density of ice is open to doubt.

Cooke (Trans. Roy. Soc. Canada, 1902, 8 [iii.] 127), in a discussion of these and earlier results, advances the view that the differences arise from stresses produced in the mass of ice by certain modes of freezing, but it is evident that Nichols' results with icicles discount this hypothesis. Vincent, measuring directly the upward pull exerted by a mass of water or ice completely immersed in mercury, confirmed generally the lower value for artificial ice, but obtained very definite evidence that the same specimen of water can, on different occasions, freeze into specimens of ice having distinctly different densities.

Further investigation is clearly needed on this point, and in the meantime the density of ice may perhaps best be taken at the mean value of 0.917.

Leduc has attempted to show that the observed differences may be due to variation in the content of dissolved air, but this explanation seems inadequate, especially in view of Vincent's results; he finds ice prepared by repeatedly freezing *in vacuo* water previously boiled to expel gases has a density of 0.9176 (Compt rend. 1906, 142, 149).

The difference between the density at 0° of water, 0.99987, and ice, 0.917, nearly 13 p.c.,

is a measure of the great expansion which takes place when water is frozen. Many important practical consequences of this expansion are well known. Freezing water produces disruptive effects in the cells of plant and animal tissues and in pipes and containers of all sorts, and these effects, occurring in the crevices of rocks, stones and buildings, and of the soil, cause progressive superficial disintegration. When water is cooled by contact with cold air, ice is formed, and because of its lower density remains, on the surface; the temperature of the bulk of water does not fall below 4°C., the temperature of maximum density, at which cooling by convection ceases. When water in process of cooling is continuously mixed, as in running streams, and free radiation occurs from the bed-rock to a clear atmosphere through shallow water, the temperature of the bed-rock and the water in contact with it may fall below 0°, when the so-called 'ground,' 'anchor' or 'frazil' ice is formed at the bottom.

Freezing of Water in Capillary Systems.—Much of the water of soils and inorganic gels fails to freeze, even at temperatures as low as -78°, because it is physically adsorbed, chemically combined, or in solid solution. E. A. Fisher (J. Physical Chem. 1924, 28, 360) points out that water present in very fine capillary tubes or pores must be under considerable tension, and so the density may not necessarily be the same as that of water in bulk, but probably less. Hence the expansion on freezing will probably be less, and since the amount of water which fails to freeze is determined by dilatometric measurements, false conclusions may thus be drawn (Chem. Soc. Abstr. 1924, 126, ii, 391).

Temperature of Maximum Density.—The data given in Tables 11 and 12 show the well-known fact that water attains a maximum density at about 4°C. Precise investigation has fixed the temperature as 3.98° at atmospheric pressure (Chappuis, Wied. Ann. 1897, 63, 202; Thiesen, Scheel and Diesselhorst, Wiss. Abh. Phys.-Tech. Reichsanstalt, 1900, 3, 68; de Coppet, Ann. Chim. 1903, [vii.] 28, 145).

At higher pressures the temperature of maximum density of water falls progressively in the manner shown in Table 17, and expressed in the following formula (Lussana, Nuovo Cim. 1910, [v.] 19, 182)

$$t_m = 4.10^\circ - 0.0225(p-1)$$

TABLE 17.
VARIATION OF THE TEMPERATURE OF MAXIMUM DENSITY OF WATER WITH PRESSURE.

Pressure.	Temperature of Maximum Density.	
1 atmo.	4.08°

2.85 "	3.9	
4.06 "	3.8	Grassi, Ann. Chim. 1851,
5.5	3.7	[iii.] 31, 437.
6.9	3.6	
8.6	3.5	
10.5	3.4	
41.6 "	3.3	Amagat, Compt. rend.
93.3 "	2.0	1893, 116, 943.
144.8 "	0.6	

For this reason in specifying water at its temperature of maximum density as the standard of density, it is necessary to stipulate that the pressure must be normal. It is also lowered by the presence of dissolved salts. For a given salt, the lowering is proportional to the concentration of the solute (Law of Despretz, *Ann. Chim.* 1839, [ii.] 70, 49; 1840, [ii.] 73, 296), but it is not connected with the depression of the freezing-point and is not a colligative property (Rosetti, *Ann. Chim.* 1867, [iv.] 10, 461; 1869, [iv.] 17, 370). The molecular lowering of the temperature of maximum density by salts of monovalent ions (e.g. H⁺, Li⁺, Na⁺, K⁺ and NH₄⁺ with Cl⁻, Br⁻, I⁻ and NO₃⁻) does exhibit a regularity in that it can be calculated from the molecular lowering of HCl (the lowest) by adding two numbers, characteristic respectively of the particular base and acid present (Wright, *J. Chem. Soc.* 1919, 115, 119): weak acids, and the salts of divalent acid and basic radicles, show no such regularity (de Coppet, *Ann. Chim.* 1894, [vii.] 3, 246, 268; *Compt. rend.* 1897, 125, 533; 1899, 128, 1559; 1900, 131, 178; 1901, 132, 1218; 1902, 134, 1208).

THE RELATION OF VOLUME AND PRESSURE FOR WATER AND ICE.

The effect of large variations of pressure upon the volume of water or ice is usually expressed in terms of the compressibility coefficient β where

$$\beta = \frac{1}{V_1} \times \frac{V_1 - V_2}{p_2 - p_1}$$

where V_1 = the volume at an initial pressure p_1 ,

and V_2 the volume at a higher pressure p_2 , at the same temperature; β is evidently the fraction by which the original volume is reduced for unit increase of pressure.

Table 18 gives the values of $\beta \times 10^6$ for water according to Amagat for pressures from 1-3000 atmospheres and temperatures from 0°-200°C. Table 19 gives the results, more accurately, but relating to a much smaller range of temperature and pressure, obtained by Richards and Stull and by Tyrer, and, for comparison, those of Bridgman at 0° and 22°.

The same data can, of course, be expressed in terms of specific volume, and Table 20 gives this quantity for water over a range of pressure from 0-12,000 kgm./cm.² and from -20° to +80°C.

Normal liquids show a compressibility which decreases with rise of pressure and increases with rise of temperature. These data show that the compressibility of water is thus affected by rise of pressure, but that increase of temperature up to about 50° lowers the compressibility; at higher temperatures the compressibility of water increases with rise of temperature like that of other liquids. The significance of this fact in relation to current hypotheses of the constitution of water is discussed elsewhere. The relation of the coefficient of expansion of water to pressure and temperature is given in Table 21. Experiments upon the isopiestic expansion of water at higher temperatures and pressures show that the thermal expansibility increases with temperature to a maximum value, which is the less the greater the pressure (Watson, *Proc. Roy. Soc. Edin.* 1911, 31, 456).

P. W. Bridgman, Proc. Amer. Acad. 1912, 48, 338.

Increase of pressure does not shift the temperature of minimum compressibility, but at high pressures this minimum disappears (Bridgman, *Zeitsch. anorg. Chem.* 1912, 77, 377).

Small as is the compressibility of water it has important practical effects and uses. It has been calculated that were water incompressible the mean sea-level would be 116 feet higher than it actually is, whereby about 4 p.c. of existing

land would be submerged (Tait, Proc. Roy. Soc. Edin. 1884, 12, 46; 1892, 20, 63, 141). Compression waves in water are transmitted with high velocity and are applied in the Constantinesco 'wave-power' system to attain the economical transmission of power, e.g. from a central motor to drilling machines or the like in mines, with an efficiency comparable with that of electrical transmission and with the

TABLE 21.

Amagat, Compt. rend. 1887, 105, 1120.

convenience and safety characteristic of compressed air.

The compressibility of ice at -7.03° for a range of pressure from 100–500 megabars is 0.0000120 (Richards and Speyers, J. Amer. Chem. Soc. 1914, 36, 491), or about one quarter that of water at 0° ; it does not decrease greatly with increase of pressure. The much higher value calculated by Bridgman (0.000036) probably indicates that the temperature coefficient of increase of compressibility for ice is abnormally high.

In considering the remaining physical properties of water it is convenient to take them in a systematic order for all forms of water, under the main groups, mechanical, thermal, optical and magnetic, and electrical.

MECHANICAL PROPERTIES.

Crystal Form.—Ice crystals, as exemplified by snow, can assume a great variety of forms which are commonly characterised by extreme openness of structure and consequent lightness; they are readily formed by the condensation of water vapour below 0° as hoar frost. Liquid water, if free from dissolved air, freezes to clear transparent ice which may give indications of structure by transmitted light or on melting, but has usually no external crystalline form. Solid, well-defined crystals of ice are extremely rare.

Though liquid water, if perfectly pure and free from dust, can be cooled to about -15° without solidification (Thomson, Trans. Roy. Soc. Edin. 1849, 16, 575; Sorby, Phil. Mag. 1859, [iv.] 18, 105), ice always melts at a definite and fixed temperature at atmospheric pressure,

and its melting-point is therefore used to define the zero point of thermometric scales. The melting-point is lowered by increase of pressure, and this has been adduced in explanation of the phenomenon of *regelation* or welding of separate pieces of ice, and is illustrated by the well-known experiment in which a weighted loop of wire cuts through, but does not sever, a block of ice.

Ice separating from under-cooled water forms hexagonal crystal skeletons or spherulites, according to the degree of under-cooling, and is obtained in feathery forms from very dilute solutions; but inoculation of under-cooled pure water with these forms produces identical forms of ice (Hartmann, Zeitsch. anorg. Chem. 1914, 88, 128).

The crystalline form of ice is hexagonal-bipyramidal with the axial ratio $a : c$ approximately 1 : 1.6 (Nordenskiöld, Öfv. Akad. Förh. Stockholm, 1860, 17, 439; Rinne, Ber. Sachs. Ges. Wiss. 917, 69, 57). Its X-ray spectrum has been investigated (St. John, Proc. Nat. Acad. Sci. 1918, 4, 193; Dennison, Phys. Rev. 1921, 17, 20), and the results are interpreted by Bragg (Proc. Physical Soc. 1922, 34, 98) on the assumption that the molecules are separated into positive and negative ions arranged in a hexagonal lattice in such a manner that each oxygen atom is situated at the centre of gravity of four neighbouring oxygen atoms, from each of which it is separated by a hydrogen ion situated midway between. The extremely open character of the structure is in accordance with the low density of ice.

The velocity of crystallisation of water in long tubes, 12 mm. external and 7 mm. internal diameter, increases with the degree of under-cooling as follows:—

Temp.	-2°	-3.61°	-4.67°	-5.86°	-6.18°	-7.10°	-8.19°	-9.07°
Velocity : } cm./min.	31.6	48.4	71.4	107.1	114.7	266.7	415.2	684.0

(Walton and Judd, J. Phys. Chem. 1914, 18, 722, which see for a useful summary of earlier work), but at any given temperature is retarded by the presence of dissolved acids, salts, dyes, &c. The retardation is not a colligative property of the solute, but appears to depend upon the extent to which the solute is hydrated in solution (Walton and Brann, J. Amer. Chem. Soc. 1916, 38, 317; Brann, *ibid.* 1918, 40, 1188).

Colloidal ice has been obtained by cooling

solutions of water in ether or chloroform, in some cases with the use of fatty acids or rubber as protective colloids (v. Weimarn and Ostwald, Zeitsch. Chem. Ind. Kolloide, 1910, 8, 181; J. Russ. Phys. Chem. Soc. 1910, 42, 226).

Elasticity.—A mass of ice yields steadily to pressure, e.g. a bar of glacier ice supported at the ends and loaded in the middle is slowly deflected, and ice compressed in a cylinder flows steadily, and the flow once started can be maintained by relatively small pressures (Hess,

Ann. Physik, 1902, [iv.] 8, 495). Curiously, the bar of ice when relieved from its load slowly recovers its original form. It has been shown that a bar of ice cut from a single crystal with its length perpendicular to the optic axis is brittle and does not yield to tension or pressure (McConnel, Proc. Roy. Soc. 1891, 49, A. 323), and the behaviour of ordinary ice is therefore

probably attributable to slipping of crystal layers of finite thickness.

The conflicting results of earlier investigators are thus explained, and it is necessary only to record the determinations of modulus of elasticity E and bending moment B in grm. cms. made by Hess (L.c.) upon bars of ice cut from single crystals as tabulated below :

Elasticity of Ice.

Load in gm. on beam 1.2 cm. × 2.5 cm. × 4-16 cm.	Length parallel to crystal axis			Width parallel to crystal axis			Thickness parallel to crystal axis		
	2000	5000	6000	1000	2000	3000	1000	1500	2000
$E \times 10^{-10} =$	0.54	0.70	0.75	3.5	2.9	4.0	1.6	2.0	2.0
$B =$	1350	3400	4000	1500	3000	4450	1600	2350	3100

The recovery of bent ice on removal of stress is much greater than similar effects in other substances, and has not been adequately explained.

The rate of plastic flow of ice is small at low temperatures, but increases rapidly near the melting-point (Tammann, Ann. Physik, 1902, [iv.] 7, 198; Slatowratsky and Tammann, Zeitsch. physikal. Chem. 1905, 53, 341), and a similar variation characterises the hardness of ice. On Mohs' scale the hardness is about 1.5, but as measured by the penetration of a steel rod into a block of ice it is considerably greater at temperatures from -37° to -12° than at about -7° , and at the melting-point ice becomes relatively quite soft (Andrews, Proc. Roy. Soc. 1886, 40, A. 544).

Frictional resistance to motion on the surface of ice is clearly related to the above phenomena; it is greater for small pressures than for large, the respective values of the coefficient of friction being 0.36 and 0.17 (Morphy, Phil. Mag. 1913, [vi.] 25, 133).

Liquid water appears to have, like some other liquids, tensile strength. If a glass tube containing only water and its vapour and nearly filled with the former be warmed until the liquid thus expanded just fills the tube, and then allowed to cool, the water continues to fill the tube even when its volume is thereby greater by about $\frac{1}{100}$ th than that corresponding to its temperature. It is hence calculated that the tensile strength of water is some 700-900 lbs./sq. in. (Berthelot, Ann. Chim. 1850, [iii.] 30, 232; see also Budgett, Proc. Roy. Soc. 1912, 86, A. 25). The rupture of a stream of water flowing through a constriction in a pipe is probably a true tensile rupture, especially as the tensile strength, deduced from the velocity at which rupture occurs, diminishes with rise

of temperature and becomes zero at about 250° (Skinner and Entwistle, Proc. Roy. Soc. 1915, 91, A. 481; Skinner and Burfitt, Proc. Physical Soc. 1919, 31, 131), in accordance with Larmor's calculation from van der Waal's equation that the tensile strength of water could subsist only up to about 265° (Larmor, Proc. London Math. Soc. 1916, [ii.] 15, 191).

The compressibility of water has already been discussed in relation to the attendant volume change, but it must here be noted that it connotes a *bulk elasticity* which is related in the usual manner to the velocity of sound in the medium. Experimental determinations of the velocity have given the following results: At 8.1° , 1435 metres/sec. (Colladen and Sturm, Ann. Chim. 1827, [ii.] 36, 113, 225; Pogg. Ann. 1828, 12, 39, 161); at 3.9° , 1399 m./sec.; at 13.7° , 1437 m./sec.; at 25.2° , 1457 m./sec. (Martini, Wied. Beibl. 1888, 12, 566; Nuovo Cimento, 1909, [v.] 18, 441).

The velocity of sound in water vapour is 401 m./sec. at 0° (Masson, Compt. rend. 1857, 44, 464; Phil. Mag. 1857, [iv.] 13, 533), and about 410 m./sec. at 100° (Jäger, Wied. Ann. 1889, 36, 165).

Viscosity.—The viscosity of water vapour has been determined at about the ordinary temperature by several observers with substantially concordant results as follows:—

At 0° , $\eta = 90.4 \times 10^{-6}$ C.G.S. units; at 16.7° , $\eta = 96.7 \times 10^{-6}$ (Puluj, Sitzungsber. Akad. Wiss. Wien. 1878, 78 (2), 279); at 18.8° , $\eta = 97.5 \times 10^{-6}$ (Kundt and Warburg, Pogg. Ann. 1875, 155, 337, 525); at 28.9° , $\eta = 100.6 \times 10^{-6}$ (H. Vogel, Ann. der Physik, 1914, 43, 1235).

For undercooled water below 0° the most probable values of the viscosity are those given in Table 22; for water from 0° – 100° substantially

TABLE 22.

Temperature	Viscosity η	Temperature	Viscosity η
20.0°	0.01003	-2.10	0.01930
15.0	0.01139	-4.70	0.02121
10.0	0.01307	-6.20	0.02250
5.0	0.01523	-7.23	0.02341
0.00	0.01798	-8.48	0.02458
		-9.30	0.02549

concordant determinations are recorded by a number of observers, and the more important are given in Table 23. The viscosity progressively diminishes with rise of temperature both as these data show and above 100° (becoming 0·00223 at 124° and 0·00181 at 158°: Hosking; Bingham and White; Table 23), but the variation does not follow any simple law and can only be expressed by empirical formulae which it is unnecessary to record.

Water under high pressures of the order of 400 atm. is less viscous than uncompressed water

at temperatures up to about 35°; at higher temperatures the viscosity of water is increased by increase of pressure, just as is that of most other liquids at all temperatures (Hauser, Drude's Ann. 1901, 5, 597).

The viscosity of ice, regarded as a fluid, has been estimated from the movement of glaciers to be of the order of $200\text{--}300 \times 10^{12}$ (Deeley and Parr, Phil. Mag. 1913, [vi.] 26, 85; 1914, [vi.] 27, 153), but measurements on blocks of ice or single crystals give widely divergent results (see e.g. McConnell, Proc. Roy. Soc. 1890, 48, A

259). Hess found that the apparent value of the viscosity depends upon the direction of flow in relation to the original crystal axis, and varies also with time in the manner indicated by the results given in Table 24. It would appear that even a single crystal of ice may yield by slipping on cleavage surfaces, with consequent recrystallisation similar to that which is familiar in the case of metals yielding to stress.

Surface tension.—Water has a higher surface tension than any other common liquid except mercury. No data are available for its value in undercooled water; Table 25 gives the values of α , the specific cohesion, and of γ , the surface tension in dynes/cm., at 1° intervals of temperature from 0°–90°; the progressive

diminution of γ with rise of temperature may be expressed by $\gamma = 76\cdot09 (1 - 0\cdot002026t)$ (Santia, Journ. de Physique, 1897, [iii.] 6, 183), or better, by $\gamma = \gamma_0 (1 - 0\cdot00190179t - 0\cdot000002499t^2)$. (Forch, Ann. Physik, 1905, 17, 744; see also Reinhold, Ber. 1913, 15, 903). Whilst the relative values of the surface tension at different temperatures are well represented by Table 25, the absolute values may be in error; in very careful measurements of the capillary rise (Richards and Coombs, J. Amer. Chem. Soc. 1915, 37, 1656; Richards and Carver, *ibid.* 1921, 43, 827) and of the 'drop-weight' of water (Harkins and Brown, J. Amer. Chem. Soc. 1919, 41, 499) a number of sources of error incidental to both methods have been discovered and eliminated, and the final results

TABLE 23A.

VISCOSITY OF WATER, γ IN C.G.S. UNITS IN THE NEIGHBOURHOOD OF ITS POINT OF MAXIMUM DENSITY.

Thorpe and Rodger (*loc. cit.*) have determined by the tube method the Viscosity of Water at various Temperatures in the vicinity of its point of maximum density, with the results seen in the annexed table.

Mean temp.	γ		Difference.
	Observed (mean).	Calculated.	
0			
0.37	-01757	-01757	-00000
1.13	-01710	-01712	+00002
1.86	-01670	-01671	+00001

7.41	-01401	-01401	-00000
8.01	-01377	-01375	-00002

[Note on Table 23a: The viscosity of water at different temperatures has also been determined by the rotating cylinder method by Leroux (Ann. Physique, 1925, [x.] 4, 163), the water being contained between two concentric cylinders, of which the outer is rotated at known velocity and the resulting twisting moment on the inner cylinder measured.

Moritz (Pogg. Ann. 70, 1847), from observations made by the method of Coulomb (oscillating disc), inferred that water had a maximum viscosity in the neighbourhood of 4°. Other observers, and more especially Poiseuille and Sprung, using the tube method, were unable to detect any peculiarity in the rate of change of viscosity at temperatures at about the point of maximum density. The observations of Thorpe and Rodger lend no support to the conclusions of Moritz. It must be borne in mind, however, that the anomalous change in the density of water amounts only to about 1 part in 10,000; hence, since the accuracy attained in these special observations of viscosity probably does not exceed 1 in 5,000, it may be doubted whether any anomalous change in viscosity of the same order of magnitude as that observed in the case of the density would be detected by any of our present experimental methods.]

TABLE 24.

VISCOSITY OF ICE, $\gamma \times 10^{10}$ C.G.S. UNITS, FOR VARIOUS ORIENTATIONS, PRESSURES AND TIMES.

Relation of beam to axis of crystal	Length parallel to axis			Width parallel to axis			Thickness parallel to axis

H. Hess, Ann. Physik. 1902, [iv.] 8, 405.

show respectively $\gamma_{100} = 72.75$ and $\gamma_{100} = 72.800$ respectively. Richards and Carver (*l.c.*) have proved experimentally, by a very ingenious optical method, that the surface of water is actually tangential to a properly wetted glass surface, and thus that the ordinary formula connecting surface tension and capillary rise holds precisely. Minute traces of dust or impurities have a considerable effect on the

surface tension, and precise measurements can only be made in a totally enclosed apparatus; Harkins and Brown have found that the capillary rise is affected by 'steaming' the tubes beforehand with the vapour of the liquid under investigation.

Absorbed or dissolved gases affect the surface tension; Richards and Carver find $\gamma_{100} = 72.73$ in air as compared with 72.75 in *vacuo*; dis-

TABLE 25.

SURFACE TENSION OF WATER.

Volkman, Wied. Ann. 1880, 11, 177; 1882, 17, 353; 1895, 56, 457 (0°-40°).

Brunner, Pogg. Ann. 1847, 70, 481 (40°-80°).

solved CO₂, CO, N₂O, H₂S, H₂O, and N₂ similarly cause a small lowering of the surface tension (Quincke, Pogg. Ann. 1870, 139, 1, 89; 1877, 160, 337; Volkman, Wied. Ann. 1880, 11, 177; 1882, 17, 353; 1894, 53, 653; 1895, 56, 457; 1898, 66, 220; Forch, Wied. Ann. 1899, 68, 801; Ann. Physik, 1905, [iv.] 17, 750; Bhatnagar, J. physikal. Chem. 1920, 24, 716).

By measurement of the amplitude of the wave produced when a stream of water emerges under pressure from capillary of elliptical cross-section, evidence has been obtained that the surface tension in a freshly formed surface of

water is about 0.5 dyne/cm. less than in old surfaces (Meyer and Stocker, Zeitsch. Elektrochem. 1916, 22, 5; Stocker, Zeitsch. physikal. Chem. 1920, 94, 149).

From the cooling effect of adiabatic expansion of water, the internal pressure has been calculated to be 2150 atmospheres (Parsons and Cook, Proc. Roy. Soc. 1911, A. 85, 332).

The surface tension in the interface between water and several organic liquids is given in Table 26; it is always less, and usually much less, than in pure water.

The coefficient of diffusion of water vapour

at 760 mm.

(II), and in cm.²/sec. is given in Table 27.

Molecular data have been calculated as follows for water vapour at 0°:

Mean molecular velocity, 58,650 cm./sec.

Mean free path, at 760 mm. press. 4.04×10^{-8} cm.Molecular diameter, about 4.0×10^{-8} .The number of molecules per gram-molecule of liquid water is estimated to be 8.5×10^{23} (Sand, Trans. Faraday Soc. 1919, 15, 94).

TABLE 26.

THERMAL PROPERTIES.

Conductivity.—The principal data for the thermal conductivity of liquid water are given in Table 28; the considerable variation among them is a measure of the difficulty of making a precise measurement of the conductivity, owing to the effects of convection and radiation, but it is clear that it is very small as compared with that of metals, yet greater than that of other non-metallic liquids (e.g. alcohol 0.00055; benzene 0.00033). The conductivity shows a linear increase with temperature and may be represented by conductivity = $0.001326(1 + 0.002954t)$ Cal./cm. sec. degree (Jakob, *loc. cit.*).

The thermal conductivity of solid ice is about four times that of water, the most probable of the recorded values being 0.0057 (Neumann,

Ann. Chim. 1862, [iii.] 66, 183; Phil. — 1863, [iv.] 25, 63), 0.0052 (Straneo, Atti Accad. Lincei, 1897, [v.] 6, (2), 262), and 0.0052 at 0°; 0.0058 at -57°; 0.0052 at -117° (Lees, Phil. Trans. 1898, 191, A. 399; Proc. Roy. Soc. 1905, 74, 337); in all cases gm. calories transmitted per sec. per sq. cm. through a thickness of 1 cm. for 1° temperature drop.

As a matter of common experience the thermal conductivity of snow is much less than that of ice, but it varies considerably with the nature and density of the snow, and attempts to measure it have given widely diverse results. Approximately it is of the order of $\frac{1}{10}$ th to $\frac{1}{15}$ th that of ice (Andrews, Proc. Roy. Soc. 1881, 40, 544; Abels, Rep. Meteorol. Acad. Petrograd, 1892, 16, 53; Hjelström, Oef. Akad. Stockholm, 1889, 46, 669; Jansson, *ibid.* 1901, 53, 207; Okada, J. Meteorol. Soc. Japan, 1906, 341).

Change of State.—The general relation of the state of aggregation to temperature has been discussed, but reference should be made to the undercooling of the liquid and vapour and the superheating of the liquid.

In the absence of nuclei, water vapour may be cooled much below its saturation temperature without deposition of visible water. Solid nuclei, such as particles of dust, spores, &c., may, and in ordinary air do, cause the condensation of liquid water immediately the saturation temperature is reached. Even less tangible nuclei will suffice. C. T. R. Wilson's simple and ingenious method of rendering the track of α -particles in a gas susceptible to visual observation or photographic record depends upon the fact that gaseous ions (produced by collision between the α -particle and molecules) will act as nuclei for the condensation of super-saturated water vapour.

Similarly, pure water in *vacuo*, in fine capillary tubes, or covered with petroleum, may be cooled some 15° below zero without solidification; even when slightly undercooled, water may be caused to crystallize by mechanical shock or agitation in the absence of nuclei (S. W. Young, J. Amer. Chem. Soc. 1911, 33, 146; Young and Cross, *ibid.* 1911, 33, 1375; Young and van Sicken, *ibid.* 1913, 35, 1067; Hartley and Thomas, J. Chem. Soc. 1906, 89, 1013). There is thus for water no evidence of the so-called 'metastable,' as distinct from 'stable,' condition in which nuclei are essential to crystallisation.

Liquid water is readily superheated; it is indeed difficult to boil water without slight local superheating, and very frequently the superheating is so considerable that when steam bubbles originate they increase in size with explosive violence, producing 'bumping.' In fresh distilled water minute bubbles of dissolved

air expelled on heating serve as nuclei for steam bubbles and minimise the bumping, and the same effect is frequently attained artificially by introducing air-filled porous solids, e.g. broken pottery, or a fine stream of air into the liquid. Without special precautions air-free water can be heated to 130° (see e.g. Donny, Ann. Chim. 1844, [iii.] 16, 167; Gernez, *ibid.* 1875, [v.] 4, 335; Krebs, Pogg. Ann. 1868, 133, 673; 1869, 136, 144; 1869, 138, 489), and if it is suspended in a mixture of olive oil and linseed oil of its own density it may be heated to 178° without boiling (Dufour, Ann. Chim. 1863, [iii.] 66, 370).

Latent Heat.—Heat is absorbed and rendered 'latent' both in the fusion of ice and in the evaporation of ice or water.

Table 29 gives the values of the heat of evaporation of water (frequently and more conveniently called the latent heat of steam) determined by a number of independent investigators at various temperatures from 0°–180°. The value at 100° is an important constant, and for this the most probable round value is 539.0 15° gm. cal. per gram.

Table 30 similarly gives data for the latent heat of fusion of ice, which usefully can be, but commonly is not, called the latent heat of water. Bunsen's value is undoubtedly erroneous, but if corrected for the difference in density between old and new ice (g.c.) becomes 79.67 in good agreement with more recent determinations. The rounded value 79.7 may be used with confidence for most purposes.

There is, of course, a direct relation between the latent heat of steam or water and the effect of dissolved substances upon the boiling-point and freezing-point.

The molecular elevation of the boiling-point is 0.52° (Beckmann, *Zeitsch. physikal. Chem.* 1891, 8, 223; 1908, 63, 177), and the molecular

Specific Heat.—The specific heat of steam at the temperature and pressure of saturation and at higher temperatures or lower pressures (when it is unsaturated or 'superheated') is of great theoretical and practical importance in connection with the generation of steam and its use in all types of prime movers. Table 31 gives the values at temperatures from 80°-550° and under pressures from 0.5 to 30 atmospheres. The specific heat of saturated steam increases

with temperature and pressure; that of unsaturated steam at constant pressures less than about 9 atmospheres decreases to a minimum value and then increases progressively with temperature; the minimum of specific heat occurs at temperatures which increase with pressure, and may occur at pressures above 9 atmospheres at higher temperatures than have yet been subject to experiment.

The specific heat of steam at or near

Knoblauch and Batsch, Zeitsch. Ver. Ing. 1922, 66, 418; based on previous work by Knoblauch et al.

atmospheric pressure has been measured at still higher temperatures; up to 1400° it is represented by $C_{p, \text{atm}} = 0.4669 - 0.0.168t + 0.0.44t^2$ or $C_{p, \text{atm}} = 0.4644 + 0.006925 \times 10^{-6} t^3$ (Holtz and Henning, Ann. Physik, 1907, [iv.] 23, 309; see also Ann. Physik, 1905, [iv.] 78, 739; Wilm. Abh. Phys.-Tech. Reichsanstalt, 1905, 4, 131; and Lorenz, Phys. Zeit. 1904, 5, 353). The ratio of the specific heats at constant pressure and constant volume is about 1.3 at 103°

1.330 at 110°, 1.313 at 120°, and 1.312 at 130° (Treitz, Bonn. 1903).

The heat capacity of water, usually at 15°, is used as a standard, and its variation with temperature is therefore of great practical importance and has been the subject of many precise investigations. Some of the more important results are given in Table 32 (see also, *inter alia*, Lötlin, Mitt. naturw. Ges. Winterthur, 1906; Dietrich, Ann. der Physik,

1902, [iv.] 16, 592; Barnes, Phil. Trans. 1902, A. 192, 149; Barnes and Cooke, Phys. Review, 1902, 15, 65; Cotty, Ann. Chim. 1911, [viii.] 24, 282).

With rise of temperature from 0°C. the specific heat decreases rapidly to a minimum value and then increases more slowly at a rate which itself increases but slightly with temperature; the measurements of Callendar and of Jaeger and Steinwehr agree in placing the minimum of specific heat at about 35°.

Numerous formulae have been proposed to express the variation of the specific heat of water with temperature, but they have no physical basis; as an example, the formula $C_p = 1.00733 - 0.0007416t + 0.000016845t^2$

$$- 0.000,000,09552t^3$$

where $C_{p,0} = 1$, agrees well from 0°–100° with the best experimental values (Narbutt, Zeitsch. Physik. Chem. 1918, 19, 513).

Below 0° the specific heat of undercooled

water increases very rapidly with fall of temperature, attaining the value 1.0155 at –5° (Barnes, l.c.).

The specific heat of water at 0° is decreased by 0.0001025 if the pressure is increased by one atmosphere.

The specific heat of ice is less well known; it is about half that of water at 0° and becomes quite small at low temperatures. A number of determinations are given in Table 33. It appears to increase very rapidly just below the melting-point (A. W. Smith, Phys. Review, 1903, 17, 193), probably owing to physical inhomogeneity.

Entropy.—The entropy of ice at 0°, calculated from absolute zero, is found to be 9.96 per gram molecule; adding 5.26 the entropy of fusion of ice at 0°, and 1.58 that due to heating water from 0° to 25°, the entropy of water at 25° is 16.8 per gram molecule (Lewis and Gibson, J. Amer. Chem. Soc. 1917, 39, 2575).

OPTICAL PROPERTIES.

Crystalloluminescence.—It has been reported that if water be rapidly frozen, bright flashes of luminescence are observed (Trautz, Zeitsch. physikal. Chem. 1905, 53, 9).

Colour: absorption of light.—There is much evidence, irrelevant here, that the bright blue colour often observed in water, notably in that of china-clay settling pits, reservoirs for large scale water-softening, and some lakes, e.g. Lake Geneva, is due to the scattering of light by

Hottner, Ann. Physik. 1913, 55, 495.

WATER.

minute suspended particles. But glacier ice and the water produced therefrom, which are undoubtedly very pure, show by transmitted light a distinct greenish-blue colour (H. Davy, Collected Works, 1840, 9, 199; Bunsen, Pogg. Ann. 1851, 83, 197; Rayleigh, Nature, 1910, 83, 48).

Pure distilled water in a tube several metres long and blackened internally is quite definitely greenish-blue by transmitted light.

As ozone is deep blue, liquid oxygen pale slightly greenish-blue, and hydrogen peroxide, methyl alcohol, ethyl alcohol and similar simple hydroxyl compounds are bluish-green, this colour is probably an intrinsic property of pure water. In smaller thicknesses water appears colourless.

The absorption spectrum of water in the visible region accords with its observed colour. In the red from 660-640 μ the absorption coefficient is about 0.3, in the orange at approximately 600 μ it is about 0.15, whence it falls rapidly to about 580 μ , and is less than 0.05 throughout the regions of the spectrum from yellow to violet (von Aufsess, Die Farbe der Seen, München, 1903). The absorption in the ultra-violet has been studied by Kreusler (Ann. der Physik. 1901, [iv.] 6, 412).

Water is opaque to infra-red radiation over a wide range of wave-length. The most recent measurements are given in Table 34 (see also Bode, Ann. Physik. 1909, [iv.] 30, 326; von Bahr, Ber. 1913, 15, 731; and, for the fine structure, Sleator, Astrophys. J. 1918, 48, 125; Wichmann, Physikal. Zeitsch. 1921, 22, 535; Ann. Physik. 1922, [iv.] 66, 501).

Water vapour is more transparent than liquid water to infra-red radiation. The opacity of the atmosphere to such radiation is mainly due to its content of water vapour, and does not extend to wave-lengths shorter than about 11 μ ; the absorption by an equivalent layer, say 2 cm., of liquid water is complete down to 1.2 μ . The difference gave rise to prolonged controversy between Magnus and Tyndall before its nature was established (Magnus, Pogg. Ann. 1861, 112, 497; 114, 635; 1863, 118, 575; 1864, 121, 186; 1866, 127, 613; 1867, 130, 207; Tyndall, Proc. Roy. Soc. 1860, 10, 37; 1861, 11, 558; 1879, 30, 10; 1881, 31, 307, 478; 1883, 35, 21; Phil. Mag. 1861, [iv.] 22, 377; 1862, [iv.] 23, 252; 1863, [iv.] 26, 44; 1866, [iv.] 32, 118; 1867, [iv.] 33, 425).

Water also absorbs X-rays (for details, see Hewlett, Phys. Review, 1921, 17, 284; Richtmyer, *ibid.* 1921, 18, 13).

Refractive Index.—Table 35 gives the refractive index of water for light of various wave-lengths and at temperatures from 0°-80°; these values are substantially confirmed by more recent and very precise determinations, which give, for the iron line E ($\lambda=5270.11$)

$$n_D^{15^\circ} = 1.3356359$$

and, for sodium light, the following values referred to air and *in vacuo*:

Temperature .	20°	25°	30°
n_D in air .	1.33299	1.33248	1.33190
n_D in vacuo .	1.33335	1.33284	1.33225

Flatow, Ann. Physik. 1903, [iv.] 12, 85: the values given by Flatow are in substantial agreement with the determinations of other observers cited, e.g. Landolt-Börnstein, Tabellen, 1923, p. 246.

(Gifford, Proc. Roy. Soc. 1906, A, 78, 406; Baxter, Burgess and Daudt, J. Amer. Chem. Soc. 1911, 33, 893).

Temperature	0°	10°	30°	40°	50°	60°	70°
Dispersion equivalent	0.0147	146	148	145	148	147	144
Dispersive power	0.0429	439	445	438	449	448	441

(Gladstone and Dale, Phil. Trans. 1858, 148, 887; 1863, 153, 323).

Measurements with electrical waves, $\lambda=3.5$ – 4.5 cm., show that the refractive index of water increases with the wave-length and that water exhibits anomalous dispersion (Mercury, Bull. Acad. Sci. Cracow, 1911, 123).

Ice exhibits double refraction and is optically positive. The refractive indices for sodium light are for the ordinary ray 1.3091 and for the extraordinary ray 1.3104 (Pulfrich, Wied. Ann. 1888, 34, 336; cf. the values 1.3083 and 1.3133 respectively of Meyer, *ibid.* 1887, 31, 322).

Scattering of Light.—It has been shown that pure water, free from ultra-microscopic suspended particles, scatters light, and that the scattered light is polarised, but the interpretation of the phenomenon is as yet incomplete or lacking (see Einstein, Ann. Physik. 1910, 33, 1275; Cabannes, J. Phys. Chem. 1920, [vi.] 1, 129; Martin, J. Phys. Chem. 1920, 24, 248; 1922, 26, 75; 1923, 27, 558; Rayleigh, Proc. Roy. Soc. 1920, 97 A, 435; Raman, *ibid.* 1922, 102, A, 151; Phil. Mag. 1923, 45, 625).

MAGNETIC AND ELECTRICAL PROPERTIES.

Coefficient of magnetisation.—The coefficient of magnetisation for water referred to unit mass has been determined by several observers to be about -0.72×10^{-6} C.G.S. units at 20° (de Haas

T°	10°	20°	30°	40°	50°	60°	70°	80°	90°
Ω	0.9998	1.0001	1.0008	1.0018	1.0029	1.0041	1.0053	1.0065	1.0074

Electrical conductivity.—Pure water is a very poor conductor of electricity. The purest water ever obtained (see Purification) had a specific conductivity 0.043×10^{-9} reciprocal ohm (mho) at 18°.

It is calculated that the conductivity of

The dispersion equivalent $n_D - n_A$ and the dispersive power $(n_D - n_A)/(n_D - 1)$ are given as follows:

and Drapier, Ann. Physik, 1913, [iv.] 42, 673; Weiss and Piccard, Compt. rend. 1912, 155, 1234; Piccard, Arch. Sci. phys. nat. 1913, [iv.] 35, 458; see also Gray and Birse, J. Chem. Soc. 1914, 105, 2707; Hayes, Phys. Rev. 1914 (2), 3, 295). This coefficient has a temperature coefficient of about $+0.00012$ at 20°.

Ice is said to be diamagnetic (Brunner, Pog Ann. 1850, 79, 173).

Magneto-optic Rotation.—The rotation of the plane of polarisation of light by a given thickness of water in a given magnetic field depends upon the wave-length of light and upon the temperature. The specific rotation (for 1 cm. of liquid in unit magnetic field) for the D line at 18° is $\omega_{18}^D = 0.01309$ minutes of arc (Agerer, Sitzungsber. Akad. Wiss. Wien. 1905, 114, 830), and its variation with temperature is given between 3° and 98° by $\omega_t^D = 0.01311(1 - 0.00305t + 0.000305t^2)$ (Rodger and Watson, Zeitsch. physikal. Chem. 1896, 19, 357).

The molecular magnetic rotation of water at 4°C. is taken as the standard, unity, for fixing that of other liquids, their molecular magnetic rotation being then given by

$$\Omega = \frac{\omega \times \text{mol. weight}}{18}$$

Thus the variation of the molecular magnetic rotation of water is of practical importance and is illustrated by the following data (Rodger and Watson):—

absolutely pure water at 18° should be 0.038×10^{-6} mho. From the same or similar data it is calculated that the *ionisation constant*, $K = [H^+] \times [OH^-]$ for water is 0.73×10^{-14} at 18° (Sorensen, Biochem. Zeitsch. 1909, 21, 191; Sorensen and Palitzsch, *ibid.* 1910, 24, 387);

TABLE 36.

DIELECTRIC CONSTANT OF WATER, ϵ .

Temperature	λ cm.	ϵ	Reference
—	∞	76	1

17°	30	80.4	4
0	75	88.2	5

1. Cohn and Arons, Wied. Ann. 1886, 28, 454; 1888, 33, 13, 31.

2. Smale, Wied. Ann. 1897, 57, 215.

3. Turner, Zeitsch. physikal. Chem. 1900, 35, 385.

4. Bukop, Diss. Grieswald, 1911.

5. Drude, Wied. Ann. 1896, 59, 17.

It varies very much with temperature (see Noyes, Kato and 1900, 32, 164).

Ice is quite a good insulator; its specific resistance is 4865 megohms at 0° and 33,540 megohms at -17° . Thus, a cable, the insulation of which is defective through moisture, will frequently show a good insulation test when exposed to severe frost.

Dielectric capacity.—The dielectric constant for steam at 145° and 760 mm. is $\epsilon=1.00705$, and its variation with temperature is expressed by $\epsilon_t = \epsilon_0 - \alpha(t_2 - t_1)$ where $\alpha=1.4 \times 10^{-4}$ and $t_1=145^{\circ}$ (Bädeker, Zeitsch. physikal. Chem. 1901, 36, 305).

Table 36 gives a series of values of ϵ for water for different wave-lengths. The dielectric constant varies with pressure from 7-200 atmospheres by about 0.0046 p.c. per atmosphere (Falkenberg, Ann. Physik. 1920, [vi.] 61, 145).

The dielectric constant for ice for $\lambda=5000$ cm. at -18° is 3.1 (Abegg, Wied. Ann. 1898, 65, 229) and for $\lambda=75$ cm. at -190° is 1.76-1.88 (Behn and Kiebitz, Boltzmann's Festschrift, Leipzig, 1904, 610).

The ionising potential for water vapour is calculated to be 8.64 volts (Compton, Phys. Review, 1916, (2), 8, 412).

THE CHEMICAL PROPERTIES OF WATER.

Molecular constitution.—It was formerly supposed that the relatively high density of water vapour in the neighbourhood of the boiling-point and at lower temperatures connoted the presence in it of molecules more complex than H_2O (see e.g. Bose, Zeitsch. Elektrochem. 1908, 14, 269; Oddo, Gazz. chim. ital. 1915, 45, i. 319; 395), but if the experimental values are corrected for the deviation of water vapour from the ideal gas-laws and recalculated by the Clausius-Clapeyron equation the results afford no evidence whatever for any deviation from the simple formula H_2O , and this must, therefore, be assumed to represent correctly the molecular state of water vapour (Kendall, J. Amer. Chem. Soc. 1920, 42, 2477; Menzies, *ibid.* 1921, 43, 851).

On the other hand, experiments with a modified Wilson's expansion apparatus, interpreted in accordance with Lenard's theory, indicate the presence of about 1.9×10^{-11} p.c. of uncharged nuclei of relatively large dimensions which are most probably polymerised molecules of the type $(H_2O)_n$ or $(H_2O)_m$ (Andrén, Ann. Physik. 1917, [iv.] 52, 1).

With regard to liquid water, there is a great body of evidence pointing to the presence of complex molecules. It is now fairly generally held that the abnormality of water as compared with other liquids in so many physical properties is due to polymerisation. This explanation was first advanced by Whiting (A New Theory of Cohesion Applied to the Thermodynamics of Liquids and Solids, Harvard University, Cambridge, Mass. 1884, p. 70), who pointed out that water at 0° may contain 15-25 p.c. and at 100° 17-26 p.c. of dissolved ice, and that the observed expansion of 4 p.c. by volume in this interval is the resultant of a normal expansion of some 8-10 p.c. by volume and a contraction due to the melting of the

dissolved ice. Eight years later, Röntgen (Wied. Ann. 1892, [5] 45, 91) independently suggested that water consists of 'ice molecules' and 'water molecules,' the former being more complex but less dense than the latter.

Later, Sutherland elaborated the hypothesis still further and, possibly influenced by Traube's theory that normal liquids consist of 'liquidogenic' and 'gasogenic' molecules, supposed water to consist of single, double and triple molecules, to which he gave the names *hydrol* (H_2O), *dihydrol* (H_4O_2), and *trihydrol* (H_6O_3).

In liquid water we then have the equilibria: $2H_2O \rightleftharpoons 3H_4O_2 \rightleftharpoons 6H_6O_3$. Steam is hydrol; ice is supposed to consist chiefly or wholly of trihydrol. Because of the lower density of ice it seems probable that trihydrol is less dense than dihydrol; and our present knowledge of the crystal structure of ice (*q.v.*) accords well with the view. Whiting's theory, originally propounded simply to explain the anomalous expansion of water, has been applied successively to the other physical properties of water, and has been found to accord so well with the observed facts that its substantial truth seems clear (see e.g. Walden, Guye, Bonsfield and Lowry, Sutherland and Nernst, Trans. Faraday Soc. 1910, 6, 71-123). It is of interest to consider some examples.

The melting of ice is attended by considerable absorption of heat and decrease of volume; *ex hypothesi* then, these phenomena characterise the conversion of trihydrol to dihydrol. Therefore, in accordance with Le Chatelier's theorem, either rise of temperature or increase of pressure will tend to dissociate trihydrol and so reduce the proportion present in water. If the volume change of water on heating is the resultant of (a) contraction due to depolymerisation of trihydrol and (b) the normal expansion of dihydrol, the preponderance of (a) up to 4° (owing to the relatively higher proportion of trihydrol then present) can explain the observed net contraction between 0° and 4° . Similarly, the diminution of the proportion of trihydrol by pressure explains the lowering of the temperature of maximum density by increase of pressure.

The minimum of compressibility of water about 50° is best accounted for by Bonsfield and Lowry's extension of the hypothesis (Trans. Faraday Soc. 1910, 6, 85); they assume that monohydrol, like trihydrol, is less dense than dihydrol, and constitutes an important proportion of water above 50° . The increased proportion of a less dense and therefore more compressible constituent both above and below that temperature then accords with the observed greater compressibility (see also Richards and Palitzsch, J. Amer. Chem. Soc. 1919, 41, 63, for a discussion of this matter, and Pagliani, Gazz. chim. ital. 1920, 50, i. 186).

Similarly convincing explanations have been elaborated for the observed variations with temperature and pressure of the viscosity (Pagliani, *loc. cit.*), specific heat (Nernst, J. Chem. Soc. 1910, A. ii. 844), index of refraction (Chéneveau, Compt. rend. 1913, 156, 1972), magnetisation (Piccard, *ibid.* 1913, 155, 1497), dielectric constant (Falkenberg, Ann. Physik. 1920, [iv.] 61, 145), &c.

Measurements of the molecular weight of water by the cryoscopic and ebullioscopic

WATER.

methods in supposedly neutral solvents give no evidence of association, but in fact water does react (*vide infra*) with such solvents in a manner which renders the method untrustworthy. More reliable conclusions may be drawn from measurements upon dilute solutions in such definitely reactive solvents as phosphorus oxychloride or nitrogen tetroxide, and these give concordant values for the molecular weight approximating closely to 36, indicating the formula H_2O , (Oddo, *Gazz. chim. ital.* 1916, 46, i. 172; see also Bruni and Amadori, *Gazz. chim. ital.* 1910, 40, ii. 1). Attempts to calculate the complexity of ice molecules in solution from the variation of expansibility, compressibility and specific heat on the assumption that ice (H_2O)_n in solution in water retains its normal density lead to values for *n* around 12 (Duclaux, *Compt. rend.* 1911, 152, 1387), but this assumption is probably incorrect.

Many attempts have been made by extrapolation to calculate the properties of pure monohydrol and dihydrol, but in the present state of knowledge these are premature (see e.g. Sutherland, *J. Chem. Soc.* 1910, A. ii. 843; Oddo, *Gazz. chim. ital.* 1916, 46, i. 188).

Observations upon the formation and liquefaction of ice crystals (Skworzoff, *J. Chem. Soc.* 1911, A. ii. 970) and the phenomena of scattering of light by water suggest the presence in water of molecules of definite structure, which is intelligible on the assumption that water is actually not a simple liquid, but, at low temperatures, a solution of ice molecules in water (dihydrol). From this standpoint, the freezing-point of water is simply to be regarded as the temperature at which the concentration of trihydrol, increasing with fall of temperature, becomes equal to the solubility of trihydrol in water which, it is assumed, decreases with fall of temperature. Regulation of ice under slight pressure may conceivably occur through local

liquefaction of the ice and its resolidification on release of pressure. But neither pressure nor capillary action (alleged by Thomson, *Proc. Roy. Soc.* 1857, 8, 455; 1859, 9, 198; 1862, 11, 473; *Phil. Mag.* 1862, [iv.] 23, 497; 24, 395) are necessary, because regelation can occur under water without pressure (Faraday, *Proc. Roy. Soc.* 1860, 10, 440). On the ice solution hypothesis it is easy to understand how two blocks of ice under water may grow together by a process of solution and recrystallisation.

In addition to the evidence indicated very briefly above there is a mass of experimental work on solution which can best be explained on the foregoing hypothesis.

It is, perhaps, important to observe that if this hypothesis of the constitution of water be correct, the melting of ice, the expansion of water (at least at low temperatures), the generation of steam, &c., commonly regarded as types of simple physical change, are in fact changes of precisely the same kind as, say, the dissociation of nitrogen tetroxide or phosphorus pentachloride or the polymerisation of aldehydes, cyanogen chloride, &c., the essentially chemical character of which is never questioned. It is unnecessary to elaborate the obvious conclusion as to the validity of the distinction so frequently drawn between chemical and physical change.

CHEMICAL REACTIONS.

Dissociation and synthesis.—Water is a fairly stable compound, and is dissociated only to a small extent at about 3000°, the temperature of the oxyhydrogen flame.

In the oxyacetylene flame, which is considerably hotter, steam is largely dissociated, and the wide applicability of this flame to the welding of metals is in fact due to the consequent presence in it of free hydrogen. The following table shows the percentage dissociation of water vapour at high temperatures:—

Temperature	1124°	1207°	1290°	1432°	1510°	1590°	1695°	1984°	2370°	2488°	2561°	2656°
P.c. dissociated	0.008	0.019	0.034	0.102	0.182	0.354	0.518	1.79	4.3	6.6	9.8	11.1

The data from 1984° upwards, obtained by an explosion method, are less trustworthy than those at lower temperatures, but probably represent well enough the general trend of the reaction (Löwenstein, *Zeitsch. physikal. Chem.* 1906, 54, 715; Langmuir, *J. Amer. Chem. Soc.* 1906, 18, 1357; v. Wartenburg, *Zeitsch. physikal. Chem.* 1906, 56, 513; Bjerrum, *ibid.* 1912, 79, 513; but see Holt, *Phil. Mag.* 1907, [vi.] 12, 630).

In agreement with these facts, gaseous hydrogen and oxygen readily combine to form water when heated, when exposed to the electric spark or to a silent electric discharge, when subjected to the radiations of radioactive elements, or when exposed to ultra-violet light.

There is no evidence, though the assumption has frequently been made, that oxygen and hydrogen combine at all at ordinary temperatures in the dark, though they do so very slowly in sunlight (Baker, *Proc. Chem. Soc.* 1902, 12, 40). Isothermal increase of pressure to 50 atmospheres has no effect in promoting union (de la Roche, *Schweigger's Journ.* 1811, 1, 172; see also Degen, *Pogg. Ann.* 1836, 38, 645).

At 100° no combination can be detected in 218 days, but at 300° the formation of water is just appreciable in 65 days (Meyer and Raum, *Ber.* 1895, 28, 2904). At 400° the velocity of reaction is such that the formation of water may be recognised within a week (Bone, *J. Chem. Soc.* 1902, 81, 535; 1904, 85, 694), and thereafter the velocity of the reaction increases rapidly with temperature until at about 510°–560° explosive combination occurs. The precise value of the ignition temperature depends on the composition of the explosive mixture (being lowest, 507°, when the ratio $H_2 : O_2 = 1 : 4$) and falls with increase of pressure (Dixon and Coward, *J. Chem. Soc.* 1906, 95, 514; Dixon, *ibid.* 1910, 97, 661), but depends also upon the method of experiment and the material of the containing vessels. A small proportion of water vapour is essential to combination by normal combustion (Baker) or through the catalytic action of platinum (French, *Chem. News* 1900, 81, 292); oxygen and hydrogen dried with phosphorus pentoxide do not react on platinum black, and only combine slowly in contact with a platinum wire at about 800°; but the explosion flame, once started, is similar in both cases and

and dried gases (Dixon and Bradshaw, *Proc. Roy. Soc.* 1907, A, 79, 224).

Ignition of detonating gas by an electric spark is frequently a purely thermal effect, but this cannot be true of the slow combination brought about by the silent discharge (Berthelot, *Ann. Chim.* 1879, [v.] 17, 142; Deherain and Maquenne, *Compt. rend.* 1881, 93, 895, 963, 1021; Mixter, *Amer. Journ. Sci.* 1898, [iv.] 4, 51; Kirby, *Phil. Mag.* 1904, [vi.] 7, 223). A general examination of the effects indicates that the cathode column is the region of greatest chemical activity (Kirby, *Phil. Mag.* 1907, [vi.] 13, 269), and it seems probable that reaction proceeds by the ionisation of both gases, though short wave-length radiations akin to ultra-violet light may contribute to the effect.

Kernbaum has found (*Compt. rend.* 1910, 151, 319) that H_2O_2 and H_2 are produced by the silent discharge in oxygen and hydrogen mixtures, and concludes that the action of the discharge is analogous to that of ultra-violet light.

Ultra-violet light causes combination of hydrogen and oxygen and decomposes water, the reaction in either case tending to the same point of equilibrium which, for example, at 150° is that corresponding to thermal equilibrium at 1250° (Coehn, *Ber.* 1910, 43, 880; Coehn and Grote, *Nernst's Festschrift*, 1912, 136; Andréeff, *J. Russ. Phys. Chem. Soc.* 1911, 43, 1342). Water in a quartz vessel is decomposed thus even by sunlight (Kernbaum, *Compt. rend.* 1909, 149, 273; *Bull. Acad. Sci. Cracow*, 1911, A, 583).

The action of ultra-violet light in decomposing water is chiefly due to the radiation of very short wave-length ($\lambda=1900$), and is best observed, therefore, by the use of low-tension or new high-tension quartz mercury vapour lamps, which emit radiation relatively rich in rays of short wave-length (Tian, *J. Chem. Soc.* 1915, A, ii, 828; Obolewsky, *Ann. Physik*, 1912 [iv.] 39, 961).

In this decomposition pure hydrogen is at first the only gaseous product; later oxygen also is produced and accumulates until the composition of the mixture is that of detonating gas. This is best explained on the assumption that the primary action is an auto-oxidation producing hydrogen and hydrogen peroxide, $2H_2O \rightarrow H_2 + H_2O_2$, oxygen being formed by a secondary decomposition of the latter,

which can result from the action of moderately short wave-length radiation (λ 2500–3000) (Tian, *Compt. rend.* 1911, 152, 1012). In support of this theory, there is evidence that hydrogen peroxide formed from water-vapour in air by the action of ultra-violet rays in sunlight forms active nuclei for the condensation of moisture (Bleher, *Ann. Physik*, 1912, [iv.] 39, 1313). Contrary to suggestions which have been made, it would seem that the amount of hydrogen peroxide produced by ultra-violet light is much too small to account for the bactericidal action of the latter (see Courmont, Nogier and Rochat, *Compt. rend.* 1910, 150, 1453).

The fact that changes of potential occur at polished inert electrodes immersed in solutions of photo-sensitive colouring matters and exposed

to light may be explained on the assumption of a photochemical decomposition of the water by visible light; but there is no other evidence in support of this hypothesis (Baur and Rebmann, *Helv. Chim. Acta.* 1923, 4, 256).

The synthesis and decomposition of water by α -radiation is well established (Davis and Edwards, *J. Soc. Chem. Ind.* 1905, 24, 266; Pickel, *Zeitsch. anorg. Chem.* 1904, 38, 307; Lind, *J. Amer. Chem. Soc.* 1919, 41, 531, 551; Duane and Scheurer, *Compt. rend.* 1913, 156, 466). In a given spherical or cylindrical vessel the velocity of reaction depends only on the quantity of emanation present and the gas pressure, but the velocity diminishes with increase in the volume of the vessel and depends upon the hydrogen:oxygen ratio. There is reason to suppose that combination is preceded by collision-ionisation of both gases, but the mechanism of reaction is not well understood.

Catalytic action in the synthesis of water was first observed by Davy (*Phil. Trans.* 1817; 97, 45, 77) in the case of platinum, and has been the subject of so many investigations that its adequate discussion here would be impossible, and properly belongs to the general consideration of catalytic action.

The energy change involved in these reactions is expressed by the heat of formation of water for which the chief data are given below.

$x=68,310$. Ice calorimeter; const. pressure, $t=0^\circ$ (Schuller and Wartha, *Wied. Ann.* 1877, 2, 381).

68,390. Burning at const. pressure, $t=18^\circ$ in 15° calories (Thomsen, *Thermochem. Untersuch.* 2, 45).

68,400. Burnt in bomb; calc. to const. pressure at $t=17^\circ$ in 15° cal. (Mixter, *Silliman's J.* 1903, (4), 16, 214).

68,380. Mean result of critical recalculation of foregoing, at 18° and const. pressure, in 15° cal. (Roth, *Zeitsch. f. Elektrochem.* 1920, 26, 1, 288).

Water is decomposed by the passage of an electric current, but owing to its very low conductivity the extent of the decomposition is very small with pure water. In practice, the electrolytic decomposition of water so-called, is effected by the electrolysis of aqueous solutions of electrolytes, and according to the ionic hypothesis the production of one at least of the constituent gases at the electrodes is due to a secondary action of the discharged ions.

It has long been known that the passage of an electrical discharge through steam produces both decomposition and a sorting of the products apparently akin to electrolysis (Farrot, *Compt. rend.* 1858, 46, 180; 47, 359; *Ann. Chim.* 1861, [iii.] 61, 161; J. J. Thomson, *Recent Researches in Electricity and Magnetism*, Cambridge, 1893, 559). But both oxygen and hydrogen may appear at either or both electrodes according to the size and form of the discharge vessel, and it seems probable that the separation observed is due to effects of diffusion and gaseous flow and not to true electrolysis (Chapman and Lidbury, *J. Chem. Soc.* 1902, 81, 130; Holt and Hopkinson, *Phil. Mag.* 1908, [vi.] 16, 82).

Oxidising and reducing action.—It is common

knowledge that water acts on many metals, usually forming a basic oxide and hydrogen. The alkali and alkaline earth metals react with cold water; glucinum (beryllium), magnesium, and many rare-earth metals react with water below its boiling-point; zinc, cadmium, tin, iron, cobalt, nickel, and chromium decompose steam at a red heat, and some other metals, *e.g.* copper and lead, react only at a white heat. Mercury, silver, gold, platinum, iridium, &c., do not react at all with water.

Whilst this is broadly true for ordinary distilled water and ordinary metals, some qualification is necessary.

The very detailed and critical study which has been made of the interaction of water and air upon iron shows clearly how greatly such actions are influenced by minute traces of impurity in either water or metal, and it has been proved that water has no action on magnesium below 100° if free from air (Roberts and Brown, *J. Amer. Chem. Soc.* 1903, 25, 801), and acts extremely slowly at ordinary temperatures with sodium amalgam if free from traces of hydrogen peroxide (Baker and Parker, *J. Chem. Soc.* 1913, 103, 2060). Therefore caution must be used in regarding the observed reactions with metals, especially at low temperatures, as those of pure water. It is known that in the wet oxidation of some metals, *e.g.* zinc, hydrogen peroxide is produced and appears to take part in the reaction (*see e.g.* Smith, *J. Chem. Soc.* 1906, 89, 479).

Water can also oxidise many non-metals. Silicon is attacked by water in glass vessels at 100°, but the action is probably due to dissolved alkali (Moissan and Siemens, *J. Chem. Soc.* 1904, A. ii. 398) and occurs with pure water only at a higher temperature. Reaction of steam with carbon begins at about 850° (Farup, *Zeitsch. anorg. Chem.* 1906, 50, 276), and at higher temperatures proceeds according to the equations $C + H_2O \rightarrow CO + H_2$; $C + 2H_2O \rightarrow CO_2 + 2H_2$, with a reversible secondary reaction $CO_2 + H_2 \rightleftharpoons CO + H_2O$ (*see* Gautier, *Compt. rend.* 1906, 142, 1382). It is of great importance in the manufacture of producer-gas and water-gas (*q.v.*). Boron at a red heat similarly yields with steam boric oxide and hydrogen. At 2000° even nitrogen is oxidised by steam with the production of nitric oxide and hydrogen, $N_2 + 2H_2O \rightleftharpoons 2NO + H_2$, the mixture at equilibrium containing about 0.5 p.c. by volume of NO (Tower, *J. Amer. Chem. Soc.* 1905, 27, 1209).

Some of the lower oxides of metals, *e.g.* MnO, UO_2 , CrO , or compounds derived therefrom, *e.g.* potassium cobaltocyanide $K_3Co(CN)_6$ and molybdenous chloride Mo_2Cl_4 , are oxidised by water with liberation of hydrogen.

Thus the oxidising action of water is pronounced at high temperatures and occurs at low temperatures with powerful reducing

Towards some non-metals, notably the halogens, water acts as a reducing agent, forming the non-metallic hydride and free oxygen. This action occurs with sulphur and phosphorus, but the oxygen simultaneously forms the non-metallic oxide. Thus with sulphur above 100° the reaction

$2H_2O + S \rightleftharpoons 2H_2 + SO_2$ is induced by the equation

though, of course,

equilibrium is reached at low concentrations of H_2S and SO_2 .

Hydrolysis.—Under this heading are included many of the most important and characteristic reactions of water.

The typical case is the hydrolysis of non-metallic chlorides, *e.g.* PCl_3 , PCl_5 , BCl_3 , $SiCl_4$, &c., to form hydrogen chloride and the hydroxy acid of the non-metal, *e.g.*

$BCl_3 + 3H_2O \rightarrow 3HCl + B(OH)_3$. Similar reactions occur with the corresponding bromides and iodides, and their irreversible character constitutes an important distinguishing characteristic of non-metallic elements. The outstanding exception to this rule is the case of the halides of carbon, *e.g.* CCl_4 , CBr_4 , CH_2Br_2 , &c., which are not hydrolysed water to any appreciable extent at ordinary temperatures.

A similar, but reversible hydrolysis occurs to a greater or less extent with many metallic halides. The chlorides of bismuth and antimony are extensively hydrolysed in cold dilute aqueous solution, insoluble oxychlorides being precipitated: $BiCl_3 + H_2O \rightleftharpoons BiOCl + 2HCl$; $SbCl_3 + H_2O \rightleftharpoons SbOCl + 2HCl$, and the higher chlorides of lead, tin, titanium, &c., $PbCl_4$, $SnCl_4$, $TiCl_4$, are hydrolysed with the formation of the corresponding hydroxides, which in some cases remain in solution. Many other metallic salts, *e.g.* $MgCl_2$, $ZnCl_2$, $CuSO_4$, &c., are appreciably hydrolysed in their aqueous solutions, which thereby acquire an acid reaction. It is indeed only in the case of relatively few salts, those of strong bases such as the alkalis, with strong acids such as the halogen hydrides, nitric acid, sulphuric acid, perchloric acid, &c., that hydrolysis in solution is inappreciable. Just as the hydrolysis of the salts of weak bases with strong acids, *e.g.* $Al_2(SO_4)_3$, gives acid solutions, so that of salts of strong bases with weak acids, *e.g.* Na_2CO_3 , Na_2S , &c., causes their solution to have an alkaline reaction. It is frequently assumed that the neutral character of a solution of, say, potassium chloride, indicates an absence of hydrolysis, but this is by no means necessarily so. The neutrality of such a solution is quite compatible with extensive hydrolysis to yield equivalent amounts of acidic and basic solutes of the same type which, by the preponderance of one or other sort, give the basic or acidic character to solutions in which hydrolysis obviously occurs. This point is of importance to the theory of solutions (Vol. vi. p. 286).

The hydrolytic action of water increases with temperature, so that at a red-heat most metallic salts are completely hydrolysed by steam, *e.g.* $MgCl_2 + H_2O \rightarrow MgO + 2HCl$ (Moldenhauer, *Zeitsch. anorg. Chem.* 1906, 51, 369), and many, *e.g.* $NaCl$, which show no sign of hydrolysis in the cold, are partly decomposed.

Many binary compounds of metals with non-metals are readily and completely hydrolysed by water at ordinary temperatures, to produce the metallic hydroxide and the non-metallic hydride. The sulphides, selenides, nitrides, phosphides, and silicides of magnesium, glucinum, and aluminium are thus decomposed, and the hydrolysis of aluminium phosphide

of silicide is a convenient method for the preparation of phosphine or silicon hydride. Hydrolysis of the carbides is of special interest; some, e.g. aluminium or glucinum carbide, yield pure methane; others give various mixtures of hydrocarbons and hydrogen. The hydrolysis of calcium carbide to produce acetylene is the basis of a great industry, and that of nitrides, e.g. AlN , to produce ammonia has been employed in some processes for the fixation of atmospheric nitrogen.

Some binary compounds of non-metals, e.g. boron nitride, and the sulphides and selenides of boron and silicon, are similarly hydrolysable.

Hydrolysis of many metallic hydrides, e.g. LiH , CaH_2 , &c., yields the metallic hydroxide and hydrogen.

In organic chemistry innumerable hydrolytic reactions of importance are known, e.g. of organo-metallic compounds $Zn(CH_3)_2$, halides, esters, cyanides, etc.

Addition.—The direct addition reactions of water with basic and acidic oxides to form bases and acids occupy an intermediate position between hydrolytic action of the foregoing type and the so-called simple hydration discussed below.

Anhydrides of strong acids and bases, *e.g.* SO_3 , P_2O_5 , N_2O_5 , or Na_2O , CaO , Li_2O , &c., combine very readily with water; those of weaker acids and bases, *e.g.* B_2O_3 , SiO_2 , or ZnO , MgO , &c., react slowly or at higher temperatures. Data for the heat of hydration of typical basic oxides are given in Table 37.

TABLE 37.
HEATS OF HYDRATION OF OXIDES.

Typical examples of the heat of hydration of basic oxides, hydroxides and peroxides are given in the following table: the values given are in 16° gram-calories.

Heats of hydration	15° gram-calories	Reference
$\text{Li}_2\text{O} + \text{H}_2\text{O} \rightarrow 2\text{LiOH}$	14,400	1
$\text{Na}_2\text{O} + \text{H}_2\text{O} \rightarrow 2\text{NaOH}$	35,440	1

This type of hydration leads to a profound change in the properties of the compound, and it is generally held that the water loses its character as such and enters into the constitution of the product in the form of hydroxyl groups. Such addition, therefore, resembles hydrolysis, save that one product only results.

Hydration.—The union of water with substances to form *hydrates*, as distinct from *ice*, is characterized by the slightness of its effect upon the physical and chemical

properties of the original substance. This is especially well seen where a compound forms a series of hydrates, e.g. FeCl_3 , Na_2CO_3 , CuSO_4 , as these differ from each other only slightly in colour, solubility, &c., and not at all in chemical properties.

It is the practice to confine the term *hydrate* to compounds in which water is present in fixed and simple molecular proportions; this, however, is an arbitrary rule. We have practically no evidence as to the manner in which

water of hydration (water of crystallisation) is held in the molecule. We know simply that water is evolved from hydrates, usually at comparatively low temperatures, that it is not directly and necessarily concerned in the most characteristic reactions of the hydrated substance, and that it can frequently be replaced molecule for molecule by other solvents, *e.g.* ether or alcohol, with a minimal change in the character of the hydrate.

The ease with which water is expelled from hydrates is illustrated by its liberation by simple grinding (Gillette, Chem. News, 1911, 104, 313), and in one recorded case by the action of light (McKee and Berkheiser, Amer. Chem. J. 1908, 40, 303). It has been suggested that hydrates may retain some water in solid solution (Richards, J. Amer. Chem. Soc. 1911, 33, 888).

Water of crystallisation has many of the properties of free water. It acts like free water upon calcium carbide (Masson, J. Chem. Soc. 1910, 97, 851) and upon some metals, *e.g.* magnesium (Michailenko and Mushinsky, J. Russ. Phys. Chem. Soc. 1912, 44, 181). It exhibits the same infra-red absorption bands as water (Schaefer and Scherbert, Ann. Physik. 1916, [iv], 50, 339).

Water can pass through solid plates of crystalline hydrates (Baker and Adams, J. Chem. Soc. 1911, 99, 567) by a process apparently resembling its diffusion through solutions.

Hydrated salts are curiously akin to the solutions from which they form. Where the colour of an anhydrous salt differs from that of its solution, *e.g.* CuSO_4 , CoCl_2 , CuBr_2 , CuCl_2 , &c., the colour of the crystalline hydrate is usually that of the solution. Hydrates exhibit a definite vapour tension of water; hence, on the kinetic theory, water molecules must pass freely in and out of the crystal space lattice as they do in and out of a solution. If the pressure of water vapour above the hydrate is less than its vapour tension, the hydrate loses water and *effloresces*. Conversely, it absorbs water and may *deliquesce*.

When a salt, capable of forming several hydrates (typically $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$, which yields $\text{CuSO}_4 \cdot 3\text{H}_2\text{O}$, $\text{CuSO}_4 \cdot \text{H}_2\text{O}$ and CuSO_4) is in equilibrium with its vapour in a closed space, and water is slowly but continually removed, the pressure of aqueous vapour over the hydrate remains constant until the whole is converted to the next lower hydrate, when the vapour pressure *suddenly* drops to that characteristic of the second hydrate and maintains that

value until conversion to the third hydrate is complete. This step by step transformation, readily interpreted in terms of the phase-rule, affords a means of detecting the existence of hydrates.

If during dehydration the vapour pressure be plotted against the percentage of water in the residual solid, the existence of a hydrate will be evidenced by a flat 'platform' on the curve; a continuous curve indicates the absence of definite hydrates.

Care must be exercised in applying this method, because there is frequently a delay, or period of induction, in the rise of the vapour pressure to the value characteristic of the temperature (Cumming, *Trans. Chem. Soc.* 1910, 97, 593; Partington, *ibid.* 1911, 99, 466; Ephraim and Millmann, *Ber.* 1917, 50, 529; Ephraim and Wagner, *Ber.* 1917, 50, 1088).

Indeed, Faraday showed (Pogg. Ann. 1834, 33, 186) that whereas hydrated sodium carbonate, sodium hydrogen phosphate, and sodium sulphate readily effloresce in air, perfect crystals of these salts may be kept in air for years without change. Inoculation with the lower hydrate at once causes the vapour pressure to assume its normal value. The period of induction in dehydration receives a rational explanation if we consider that the minute particles of the second phase formed at first by dehydration have, like small drops of water, an abnormally high vapour pressure (Rae, *J. Chem. Soc.* 1916, 109, 1229; see Pavlov, *J. Russ. Phys. Chem. Soc.* 1909, 41, 679).

Table 37 contains data for the thermal effect of several typical hydration reactions. Table 38 gives the equilibrium pressure of water vapour, in mm. of mercury, at 25° over a few of the more important crystalline hydrated salts, when in equilibrium with a lower hydrate or the anhydrous salt.

Solution and ionisation.—Water is, *par excellence*, the solvent. It has been argued that all substances are soluble in water, but this is not proven. Most salts and compounds usually classed as insoluble, e.g. silver chloride, glass, silica, are well known to have a small, but definite, solubility in water. The great majority of solids and liquids, and all known gases, are distinctly soluble, and some very soluble, in it.

There is much reason to believe that the solvent power of water and its pre-eminence as an ionising solvent are both due to chemical action between solvent and solute of the kind considered under hydrolysis and hydration.

An overwhelming mass of real evidence exists that substances dissolved in water are intimately associated, one had better say combined, with water or 'solvated' (see, for a list of references, Dhar, *Zeitsch. Elektrochem.* 1914, 20, 57; and for a critical review of earlier work, Washburn, *Hydrates in Solution*, *Tech. Quart.* 1908, 21, 360; as examples of more recent evidence, see e.g. Schaeffer, Paulus and H. G. Jones, *Phys. Zeitsch.* 1914, 15, 447; Philip and Bramley, *J. Chem. Soc.* 1915, 107, 571, 1935; Kornfeld, *Monatsh.* 1915, 36, 865; Porter, *Trans. Faraday Soc.* 1917, 13, 123; Smith, Lands and Bowman, *Proc. K. Akad. Wetensch. Amsterdam*, 1921, 23, 969, and

chemists have preferred to interpret all solution phenomena in terms of such compounds, even going so far as to regard the whole of the solvent as being combined with the solute (Kahlenberg, *Trans. Faraday Soc.* 1905, 1, 42).

On the other hand, much work adduced as evidence for solvation is unconvincing and contradictory. Kendall has remarked: "In the system $\text{H}_2\text{SO}_4\text{--H}_2\text{O}$, for instance, as many as '02 different hydrates have been 'discovered,' ing in composition from $36\text{H}_2\text{SO}_4\cdot\text{H}_2\text{O}$ to $\text{H}_2\text{SO}_4\cdot 4950\text{H}_2\text{O}$. Few of these have been encountered twice by independent investigators, the opportunity for originality being almost unlimited." Thus many chemists have supported the original view of Ostwald and van't Hoff, which regards the solvent simply as a dispersive medium, enabling the solute to behave as if alone and in a gaseous state (see *Brit. Association Report*, 1890, 60, 311-338).

But the 'solvate' theory, rejecting the conception of ionisation altogether (see e.g. Armstrong and Worley, *Proc. Roy. Soc.* 1912, 87 A, 604), fails to explain in any satisfactory manner the mechanism of conduction in electrolytes, whilst the strict ionic theory equally fails to explain why and how ionic dissociation occurs.

It has been generally recognised by those who admit the existence of ions, that the ions in solution are hydrated (see Arrhenius, *Theories of Solutions*, pp. 184-195), and it has been pointed out that the rival 'solvate' and 'ionic' theories are in reality not irreconcilable but supplementary (Walker, *Brit. Association Report*, 1911, 81, 356).

There is, in fact, an intimate and general connection between ionisation and compound formation in solutions, and Kendall and Booge have strongly advocated the hypothesis that ionisation is preceded by, and is a consequence of, the formation of such compounds (Kendall and Booge, *J. Amer. Chem. Soc.* 1917, 39, 2323; this paper contains a detailed discussion of the hypothesis and numerous references to the literature, and should be consulted; the same idea had been indicated by others, to whom reference is made in the above paper, and was formulated with some precision by Bogorodski, *J. Russ. Phys. Chem. Soc.* 1914, 46, 1716).

Experiments with tetraethyl-ammonium iodide in a large number of solvents have shown that conductivity of solutions is fundamentally related to the dielectric constant and to the state of unsaturation of the simple molecules of the solvent (Walden, *Zeitsch. physikal. Chem.* 1903, 46, 103; 1906, 54, 129; H. G. Jones, *Amer. Chem. J.* 1901, 25, 232). These properties, as might be anticipated from their general parallelism, have a causal relationship (Thomson, *Phil. Mag.* 1914, [vi.] 27, 757; Lewis, *J. Amer. Chem. Soc.* 1913, 35, 1448; 1916, 38, 762).

Unsaturation implies the presence in the molecule of electrons which are free to move under the influence of an electric field. The simple water molecule (H_2O) contains two doublets, as in the formula $\text{H}^+-\text{O}^--\text{H}^+$; and the six free electrons of the oxygen atom will move into such positions as enable them to exert a maximum attractive force upon the

positive parts of these doublets, so that an unequal distribution of electric charges will result. By proximity of two such molecules this unequal distribution is accentuated and may lead to the formation of associated molecules, possessing a still larger electrostatic moment, in which the constraints are correspondingly weakened. Further association can occur with enhancement of these effects.

Great attractive forces are exerted by such associated molecules upon any solute RX ; these forces are cumulative as the molecules come into closer proximity, and can evidently lead to the formation of complexes of the type $R(H_2O)_n-X$, in which the constraints upon the electrons are still further weakened. Such complexes are much less stable than the simple component molecules and dissociable at any point, and it is thus possible to see how hydration may cause ionisation.

The essential probability of this theory is illustrated by the case of aqueous hydrochloric acid. Both hydrogen chloride and water when pure are almost non-conductors (Kohlrausch and Heydweiller, *Zeitsch. physikal. Chem.* 1894, 14, 326; Steele, McIntosh and Archibald, *ibid.* 1906, 55, 148); both contain unsaturated atoms in the simple molecule and are in consequence associated; both have high dielectric constants. When mixed they constitute a good electrolyte.

In contrast with the older ionic hypothesis, Kendall's theory permits us to regard the ionisation and conductivity as due to both constituents of the solution. Complex molecules $(H_2O)_n \cdot (HCl)_m$ are formed and dissociate to yield positively and negatively charged radicals. Taking the simplest case these would be either $(Cl \cdot H_2O)^-$ and $(H \cdot H_2O)^+$ or $(HCl \cdot OH)^-$ and $(HCl \cdot H)^+$, and on inspection these two alternatives are seen to be the same thing. The complex $(H_2OCl)^-$ may be regarded either as a hydrated chloride ion or a solvated hydroxyl ion.

The following table shows the degree of dissociation of pure water at various temperatures from 0° – 50° ; α being the weight in grms. of hydrogen ion in 1 c.c. of water at the stated temperature.

Temp.	$\alpha \times 10^{10}$
0°	0.36
2°	0.40
10°	0.57
18°	0.80
26°	1.10
34°	1.45
42°	1.91
50°	2.44

(Kohlrausch and Heydweiller, *Wied. Ann.* 1894, 53, 234; *Zeitsch. physikal. Chem.* 1894, 14, 330; the numbers are in substantial agreement with the indirect measurements of Arrhenius, *Zeitsch. physikal. Chem.* 1893, 11, 823; Nernst, *ibid.* 1894, 14, 155; Lorenz and Behl, *ibid.* 1909, 66, 748; Noyes and Kato, *ibid.* 1910, 73, 20; Dolezalek, *Zeitsch. Elektrochem.* 1899, 5, 536; Kanolt, *J. Amer. Chem. Soc.* 1907, 29, 1414; Lewis, Brighton and Sebastian, *ibid.* 1917, 39, 2260; Lunden, *J. Chem. Phys.* 1907, 5, 589; Heydweiller, *Ann. Physik.* 1909, [iv.] 28, 511).

The heat of formation of water from its ions is +14,700 gm. cal. per gm. mol. at $0^\circ C$, the value at other temperatures t , being given by +14,700–50 t . This is the most probable value derived from a number of researches by different methods, as follows:

1. From the heat of neutralisation of strong acids by strong bases (Wärmann, *Ann. Physik.* 1905, [iv.] 18, 793; Heydweiller, *Ann. Physik.* 1909, [iv.] 28, 503; Thomsen, *Thermochem. Untersuch.* 1882; Muller, *Bull. Soc. chim.* 1918, [iv.] 23, 8; Müller and Bauer, *J. Chim. Phys.* 1904, 2, 457).

2. From the change of conductivity of pure water with change of temperature; calculated by van 't Hoff from the data of Kohlrausch and Heydweiller.

3. From the variation with temperature of degree of hydrolysis of salts (Lunden, *J. Chem. Phys.* 1907, 5, 145, 574; 1908, 6, 6, 81; Noyes, *Carnegie Inst. Publ.* 1907, No. 63).
H. V. A. B.

Water in its Economic and Sanitary Relations. Drinking Water.

Water for Domestic Supply.

Water is absolutely indispensable to both animal and vegetable life; it is the cause of many of the most striking phenomena in nature, and is employed for countless purposes by man. Its distribution is as wide as that of the air itself whilst its amount on the earth is enormously greater. In an absolutely pure state it is never met with in nature. The impurities in natural water are derived from the materials—solid, liquid, or gaseous—with which it comes in contact, and they may be present either in suspension or in solution or in both. Inasmuch, therefore, as the interest attaching to different waters depends upon the impurities they contain, and these are dependent upon the matters with which they have been in contact, it is most convenient to classify waters according to their origin.

1. *Rain-water, snow, hail, dew, and hoar-frost.* All these forms of water are obtained by the condensation of the aqueous vapour which is invariably present in the air. The amount of aqueous vapour which can be contained in a given volume of air is solely dependent upon the temperature. If the atmosphere has become saturated with aqueous vapour at any given temperature and is cooled below that temperature, the excess of aqueous vapour will condense, according to circumstances, as rain, hail, snow, mist, dew, or hoar-frost. This condensation is promoted by the presence of dust and electrically charged particles. All these forms of water having been only in contact with the air and not with the earth are characterized by the small proportion of solid matter which they contain, although the amount found, especially in the vicinity of towns, is often considerably greater than would be anticipated, and the rain-water falling in the neighbourhood of the sea is often mixed to a considerable extent with sea-spray, which with favourable winds is carried many miles inland. In the following table are recorded the maximum, minimum, and average proportions of several in of rain-water collected at
where, expressed in parts per 100,000—

WATER.

	Total solid impurity	Organic carbon	Organic nitrogen	Ammonia	Nitrogen as nitrates and nitrites	Chlorine	Hardness
Minimum	0.62	0.021	0.003	0.005	0	0	0
Maximum	8.58	0.372	0.121	0.155	0.044	1.65	1.7
Average	3.42	0.095	0.021	0.049	0.007	0.33	0.5
Rain-water collected at Land's End, Cornwall, Jan. 2, 1873	42.80	0.131	0.034	0	0.020	21.8	10.0
Rain-water collected near Hyde Park, London, Nov. 8, 1873	2.76	0.383	0.040	0.210	0.008	0.5	1.1

It is thus seen that the composition of rain-water, even in the open country, is able to great fluctuations, and that the amount of impurity, both mineral and organic, occasionally surprisingly large. The amount

of organic impurity in dew and hoar-frost is still greater owing to these forms of water being condensed out of the lowest and most-contaminated couches of the atmosphere. Thus—

SEVEN SAMPLES OF DEW AND HOAR-FROST, ROTHAMSTED, 1869 AND 1870.

(Results of Analysis expressed in parts per 100,000.)

	Total solids	Organic carbon	Organic nitrogen	Ammonia	Nitrogen as nitrates and nitrites	Chlorine	Hardness
Minimum	2.64	0.195	0.026	0.130	0	0.35	1.3
Maximum	8.00	0.450	0.196	0.280	0.050	0.80	2.5
Average	4.87	0.264	0.076	0.198	0.023	0.53	1.9

Two other impurities, not referred to above, which are generally present in the rain-water and snow of towns are sulphurous and sulphuric acids derived from the combustion of coal. Angus Smith found in the rain-water of London 2.05, of Liverpool 3.96, in that of Manchester 4.48, and in that of Glasgow 7.02 parts of sulphuric acid per 100,000, to a considerable extent in the free state. Sendtner found freshly-fallen snow in Munich to contain 0.7 part sulphuric acid (SO_3) per 100,000, on the following day 1.76 parts, after 10 days 6.22 parts, and after 16 days 9.18 parts. The presence of this free acid in the rain-water of towns is, of course, not only detrimental to vegetation, but also to sculptures and buildings in which marble or limestone are employed. The proportion of ammonia increases in the snow after lying on the ground (Wagner, *Technologie*, 305).

2. *Upland surface water* most nearly approaches in composition to that of the atmospheric waters dealt with in the last section. It is, in fact, rain-water which has undergone minimum contact with the earth, although in consequence of its solvent action even this contact is sufficient to impart to the water in many cases such proportions of dissolved matter as are never found in rain-water. The amount and nature of these ingredients depend, of course, mainly upon the kind of soil over which the water has travelled, and consequently it becomes convenient to sub-divide this class according to the geological character of the ground from which the upland surface water has been obtained.

In the tables on p. 370 are recorded the maximum, minimum, and average amounts of impurity found in the examination of a large series of samples of waters principally derived from land not under cultivation, so as to represent the characters naturally acquired by water passing over the various geological formations.

The tables (I. and II.) show that upland surface waters generally contain a considerable amount of dissolved matters only when they are derived from calcareous strata. The organic matter is subject to great variation, but in every case contains only a very small proportion of nitrogen in comparison with the carbon, indicating that the organic substances present are of vegetable origin, which is further attested by the almost entire absence of ammonia, nitrates, and nitrites, all of which, when present in amount beyond that in which they occur in rain-water, are nearly exclusively derived from the decomposition of animal matters. The chlorine is also low, the gathering grounds being generally beyond the reach of sea-spray and not receiving the liquid excrements of animals, which are particularly rich in chlorides, whilst from their mere surface contact with the soil they have not extracted any considerable quantities of the salts present in the latter, as is the case with spring- and well-water.

3. *Surface water derived from cultivated land.*—This includes the great body of stream-waters, inasmuch as practically all streams flow through and receive accessions from land under cultivation before reaching the sea. The nature

¹ Owing to the compact nature of the limestone in these old formations, the hardness is very moderate.

² Hardness not excessive, but large amount of organic matter (peaty), rendering the waters coloured and unpalatable.

³ Of very variable character; generally of only moderate hardness, but containing much peaty matter, and hence coloured and unpalatable.

⁴ Slightly turbid.

⁵ Slightly turbid. Owing to the porous nature of Oolite formation, surface water is very rare.

position of such waters is very varied, depending upon local circumstances, and being liable to great fluctuations at different seasons of the year. This group may be conveniently divided into two sub-groups, according as the water

is derived from calcareous or non-calcareous districts. The following results of analyses of British waters of this description are compiled from the Sixth Report of the Rivers Commission, 1874:—

SURFACE WATERS FROM CULTIVATED LAND.

(Results of Analysis expressed in parts per 100,000.)

Description	Total solid matters	Organic carbon	Organic nitrogen	Ammonia	Nitrogen as nitrates and nitrites	Total combined nitrogen	Chlorine	Hardness		
								Temporary	Permanent	Total
(a) Water from non-calcareous districts. ¹										
Maximum . . .	18.10	1.124	0.112	0.056	0.258	0.393	2.80	4.6	8.0	10.1
Minimum . . .	5.26	0.125	0 ²	0	0	0.017	0.70	0	1.8	2.1
Average (31 samples)	9.52	0.276	0.034	0.007	0.089	0.128	1.49	0.6	4.3	4.9
(b) Water from calcareous districts. ²										
Maximum . . .	110.40	1.338	0.307	0.030	1.005	1.096	12.75	26.3	42.1	67.3
Minimum . . .	13.22	0.069	0.009	0	0	0.033	0.54	0	2.1	7.8
Average (144 samples)	30.08	0.268	0.053	0.005	0.257	0.314	2.24	12.4	8.2	20.6

¹ Usually turbid, organic matter generally moderate in amount, but partially of animal origin.

² This result is extremely improbable, more especially as the particular water in question (a sample of the water supplied to Bury and Radcliffe, Lancashire) contained 0.229 organic carbon, 0.032 ammonia, and 0.066 nitrogen as nitrates and nitrites.

³ Generally turbid, the organic matter is much the same in amount as in the water from non-calcareous districts, but generally more nitrogenous, in consequence of calcareous soils being usually under higher cultivation than non-calcareous ones. The total combined nitrogen is also for the same reason considerably greater, and the hardness is, of course, very much higher.

In connection with the effect of cultivated land upon the water with which it comes in contact, it is instructive to note the nature of the water which drains from such land, as this throws light upon the composition of subterranean waters (from springs and wells), which will be considered below.

In the following table is recorded the composition of the water obtained from drain-pipes placed from 18 ins. to 5 ft. below a plot of land at Rothamsted which had remained both unmanured and uncropped for a period of 11-15 years:—

COMPOSITION OF WATER FROM LAND UNMANURED AND UNCROPPED FOR ELEVEN TO FIFTEEN YEARS.¹ (6th Rep. Riv. Com. p. 62.)

(Results of Analysis expressed in parts per 100,000.)

Description	Total solid matters	Organic carbon	Organic nitrogen	Ammonia	Nitrogen as nitrates and nitrites	Total combined nitrogen	Chlorine	Hardness		
								Temporary	Permanent	Total
Maximum . . .	63.28	0.235	0.116	0.026	4.936	4.981	3.80	7.2	11.9	16.6
Minimum . . .	18.00	0.096	0.026	0	0.607	0.654	0.60	0.3	3.2	3.5
Average (15 samples distributed over four years) . . .	32.06	0.154	0.053	0.006	2.195	2.253	1.65	4.1	8.5	12.6

¹ The samples varied from clear to turbid.

It will be seen that the conversion of the original nitrogenous organic matter in the soil into mineral products is a very slow process, large quantities of nitrates being still present in the drainage waters after the lapse of so many years.

It is interesting to compare with the above the composition of the water draining from a plot of land unmanured for 16-21 years, but continuously bearing an annual wheat crop during that time:—

COMPOSITION OF WATER FROM LAND UNMANURED FOR SIXTEEN TO TWENTY-ONE YEARS, BUT CONTINUOUSLY BEARING WHEAT CROPS. (6th Rep. Riv. Com. p. 80.)

(Results of Analysis expressed in parts per 100,000.)

Description	Total solid matters	Organic carbon	Organic nitrogen	Ammonia	Nitrogen as nitrates and nitrites	Total combined nitrogen	Chlorine	Hardness		
								Temporary	Permanent	Total
Maximum . . .	48.40	0.242	0.058	0.006	2.268	—	3.80	14.1	22.4	32.7
Minimum . . .	13.80	0.099	0.010	0	0	—	0.80	8.9	3.9	13.5
Average (11 samples distributed over five years) . . .	24.96	0.170	0.034	0.002	0.645	—	1.37	10.8	8.4	19.2

As might have been anticipated, the proportions of ammonia and nitrates finding their way into the drainage water in this case were much less, and in the summer months during the growth of the crop the amount of this mineral nitrogen found in the drainage water was practically *nil*.

We will, in the next place, compare with the above the composition of the drainage water from land which had been manured annually with 14 tons of farmyard manure per acre over a period of 24–29 years, and bearing wheat continuously during that time:—

COMPOSITION OF DRAINAGE WATER FROM LAND MANURED WITH 14 TONS FARMYARD MANURE PER ACRE FOR TWENTY-FOUR TO TWENTY-NINE YEARS. (6th Rep. Riv. Com. p. 58.)

(Results of Analysis expressed in parts per 100,000.)

Description	Total solid matters	Organic carbon	Organic nitrogen	Ammonia	Nitrogen as nitrates and nitrites	Total combined nitrogen	Chlorine	Hardness		
								Temporary	Permanent	Total
Maximum . . .	51.20	1.243	0.335	0.052	2.592	2.754	3.35	12.1	20.6	32.1
Minimum . . .	14.00	0.181	0.036	0	0.082	0.130	0.60	1.4	5.4	8.7
Average (13 samples over five years) . . .	25.90	0.519	0.115	0.009	0.528	0.665	1.30	6.8	8.6	15.4

Thus the difference between the drainage waters from the unmanured and manured land is not nearly so great as might have been expected, being principally confined to the larger proportion of organic matter found in the latter.

The above results may be compared with

those obtained in the analysis of a number of samples of the drainage water from sewage farms, in all of which the town sewage is, or was, applied to land, with the double object of purifying the sewage and deriving a profit out of the crops raised. Thus:—

COMPOSITION OF DRAINAGE WATER FROM SEWAGE FARMS. (6th Rep. Riv. Com. pp. 55–57.)

(Results of Analysis expressed in parts per 100,000.)

Description	Total solid matters	Organic carbon	Organic nitrogen	Ammonia	Nitrogen as nitrates and nitrites	Total combined nitrogen	Chlorine	Hardness		
								Temporary	Permanent	Total
Maximum . . .	103.00	2.160	0.517	1.366	6.499	6.833	13.40	36.9	39.3	56.6
Minimum . . .	18.60	0.108	0.034	0.005	0	0.069	2.15	0	3.9	3.9
Average (72 samples)	64.02	0.982	0.191	0.388	0.756	1.266	6.36	17.6	15.4	23.0

It will be seen that the drainage water from sewage farms is generally richer in organic and inorganic impurities than the water draining from manured or unmanured land, the passage of the water through the ground being in the latter case a much slower one, and thus allowing time for more perfect purification by soil and

plants. Occasionally, as indicated by the above minimum results, the drainage water from sewage farms is remarkably free from impurities. A much purer drainage water is often yielded in the intermittent downward filtration of sewage through suitable land.

thus gained of the compos-

SHALLOW WELL WATERS.

¹ In almost all cases clear and palatable. ² Generally clear and palatable. ³ Almost all clear and palatable.

⁴ In many cases clear and palatable; but in others turbid, and even very turbid.

⁵ All clear or slightly turbid and palatable.

⁶ Generally clear, or only slightly turbid and palatable. In a few cases saline taste.

⁷ Even this water clear and palatable.

⁸ In nearly all cases clear, or slightly turbid and palatable.

⁹ Varying from clear and palatable to very turbid. In some cases saline taste.

¹⁰ Mostly more or less turbid. Palatable.

¹¹ Clear to very turbid. Palatable, or occasionally slight saline taste.

¹² Generally more or less turbid and palatable. Occasionally slight saline taste.

¹³ Generally more or less turbid and palatable.

¹⁴ More or less turbid and palatable.

¹⁵ Generally clear or only slightly turbid and palatable. Occasionally slight saline taste.

tion of waters draining from cultivated land becomes of special value in studying the nature of the next group of waters (shallow well water).

4. *Shallow well water*.—It has been estimated that about twelve millions of the inhabitants of Great Britain are supplied with water for domestic purposes from shallow wells. This class of water is very liable to serious contamination with sewage and refuse animal matters, inasmuch as such wells are almost invariably sunk in the vicinity of human dwellings, and frequently within a few feet of the cesspool receiving their drainage. It is these waters which have most frequently caused serious outbreaks of typhoid fever. In consequence of the great practical interest attaching to these waters, their composition will be considered in connection with the principal geological formations upon which such shallow wells may be sunk.

The results recorded in the previous table serve to show the general composition of shallow well waters as met with in Great Britain. The composition of these waters varies within very wide limits, even when derived from one and the same geological formation, which is due to their being not generally an aqueous extract of a soil in its natural condition, but of ground which is often saturated with sewage and other animal refuse. In consequence of the oxidising power of soil, the organic matter of this refuse is not unfrequently almost entirely destroyed before reaching the wells, and even the ammonia, which is one of the first products of its decomposition, has often disappeared, having generally become converted into nitrates and nitrites. Of nitrates and nitrites these shallow well waters generally contain some, and often a large amount, which thus, together with the ammonia,

DEEP WELL WATERS. (6th Rep. Riv. Com. p. 89.)

testify to the water having previously been in contact with nitrogenous organic matter which has subsequently undergone destruction. In shallow well waters, even when the organic matter is only small in amount, it is generally highly nitrogenous, pointing to its probable animal origin, and in some exceptional cases the organic nitrogen found is actually in excess of the carbon. These waters, which are generally suspicious from the presence of mineral nitrogen, become in the highest degree dangerous when the proportion of organic matter is large.

5. *Deep well waters.*—It is convenient to distinguish for sanitary purposes between waters which are obtained from comparatively shallow wells and those which are derived from wells, say, upwards of 100 ft. in depth, and sometimes reaching to the distance of more than 1000 ft. below the surface of the earth. The presumption is that waters obtained from such a depth have undergone perfect filtration through porous strata, and consequently it is not usual to view the evidence of previous contact with animal matters afforded by the presence of mineral nitrogen with so much suspicion as in the case of the waters from the shallower wells. The great efficiency of the filtration which most of these deep well waters have undergone is attested both by their freedom from organic matter, and from every kind of suspended material, whether organic or inorganic. In consequence of the excellent water obtainable from such deep wells, they have been multiplied greatly during past years, so that at the present time not only are many towns (including a part of London) and villages supplied from this source, but also nearly all larger breweries and many private establishments. In some cases these deep wells are of the kind known as 'Artesian' (from Artois, in France, where they were probably first employed); that is to say, on reaching the water-bearing stratum the water rises to the level or even considerably above the level of the ground, due to the underground water being confined under pressure beneath an impervious stratum of clay or the like, and through the outcrop of the water-bearing stratum being at a considerably higher altitude than the point at which the boring has been made. Thus, in the London basin, 'Artesian wells' are obtained by sinking through the London clay into the chalk beneath, which has its outcrop at considerable altitudes in the chalk hills on the north and south of the Thames valley. Owing to the large abstraction from such water-bearing strata, the water of many wells which formerly rose to the surface has now to be pumped. In the majority of deep wells the water does not rise nearly to the surface, and the pumps have often to be placed at considerable depths in the shaft. It is usual to line these wells with closely-fitting iron cylinders, in order to exclude surface water, as unless this is done the deep wells may become as objectionable and dangerous as shallow ones.

The preceding tables afford a survey of the general character of the deep well waters obtained in Great Britain. In nearly all the samples of which the maximum, minimum, and average results are given, it may be taken that the wells are unpolluted by surface water, but for the sake of comparison there are appended

to most of the sections analyses of deep well waters from the same strata in which pollution by surface or imperfectly-filtered water is highly probable.

These results demonstrate the great superiority from a chemical point of view of the subterranean waters obtained at great depths to those derived from shallow wells. Indeed, these deep well waters are, as regards organic matter, amongst the purest to be found in nature, and hence, unless extremely hard, are of the best quality for drinking purposes.

Closely associated with these deep well waters is the next group of spring waters.

6. *Spring water.*—In the following table is given the composition of, presumably unpolluted, British spring waters arranged according to the geological nature of the ground from which they are derived, whilst for the sake of comparison the composition of probably polluted waters from the same geological source is in many cases appended.

7. *Mineral spring waters.*—Many springs possess marked medicinal properties in consequence of the materials they hold in solution. Until the discovery of radium it was generally supposed by chemists that the therapeutic value of such waters containing only an insignificant amount of mineral matter must be imaginary, but it is now known that some of these, such as the waters of Bath and Buxton, are pronouncedly radioactive, and it is generally accepted at the present time that the old-established efficacy of these waters in the treatment of gout and rheumatism is due to their content of radioactive material (*see Nature*, 1911, 86, 157). Indeed, radium-salt is now much employed for the artificial production of radioactive water for medicinal purposes. An immense number of mineral waters are in use, and have been submitted to careful analysis; a very extensive collection of such analyses is to be found in Raspe's *Heilquellen Analysen*, Dresden, 1885.

These mineral waters are conveniently classified by Hermann Weber (*Quain's Dictionary of Medicine*), according to the ingredients which characterise them, into—(1) Simple thermal waters; (2) common salt or muriated saline waters; (3) alkaline waters; (4) sulphated saline waters; (5) iron or chalybeate waters; (6) sulphur waters; (7) earthy and calcareous waters.

(1) *The simple thermal waters*, whilst containing only a moderate proportion of dissolved solids, are characterised by a high temperature, from 27°–65°, and sometimes by the presence of an unusually large proportion of nitrogen, which is now known to be mixed with appreciable quantities of helium. Doubtless the medicinal reputation of most, if not all, of these waters depends on their radioactivity. The principal springs of this class are: Panticoos, Leukerbad, Bormio, Gastein, Pfäfers, Johannisbad, Ragatz, Wildbad, Plombières, Buxton, Bath, Looe, Teplitz, Schlangenbad, &c.

(2) *Common salt or muriated saline waters* contain sodium chloride as the principal constituent, although this also occurs often in large quantity in many of the other classes of mineral waters. These salt waters or brines are very common in almost all countries. Some of the

SPRING WATER. (6th Rep. Riv. Com. p. 107.)

* Water supply of Western-super-Mare; these exceptionally high results doubtless due to access of sea water.

principal ones in England are: Droitwich, Nantwich, Middlewich, Woodhall, and Harrogate; Leamington and Cheltenham along with sodium sulphate. In Germany: Kissingen, Homburg, Nauheim, Krensnach, Soden, Pyrmont, Wiesbaden, Ischl, Kreuth, Baden-Baden, &c. In France: Bourbonne-les-Bains, Lamotte-les-Bains, Balaruc, Salins. In Italy: Castellamare, Ischia, Monte Catini, La Porretta. In Switzerland: Bex.

(3) *Alkaline waters* are characterised by the presence of sodium carbonate, almost always with more or less free carbon dioxide, and sometimes with a large quantity also of sodium chloride. Of the simply alkaline waters, there are—(a) *Hot*: Vichy, Neuenahr, Mont-Dore, Chaudesaignes, Nérès; (b) *Cold*: Apollinaris, Vals, Salzbrunn, Bilin, Wilhelmsquelle, Taunus, Marco; whilst the chief muriated alkaline waters are: (a) *Hot*: Ems, Royat, La Bourboule; and (b) *Cold*: Luhatschowitz, Selters, Gleichenberg, Rosbach, Vic-sur-Cère. Several of these, but especially La Bourboule and Mont-Dore, contain a marked proportion of arsenic.

(4) *Sulphated waters* contain either sodium or magnesium sulphate, or both, as the prominent ingredients, in some cases also associated with sodium carbonate and chloride. They are often called '*bitter waters*.' The chief simple sulphated waters are: Galthof, Pullna, Said-schutz, Sedlitz, Birmensdorf, Ivanda, Hunyadi Janos, Epsom, Aranjuez, Friedrichshall, Mergentheim; the two latter are also rich in chlorides. Weaker springs of the same kind are found at Leamington, Cheltenham, Scarborough, and at Purton Spa. Of alkaline sulphated waters there are: Carlsbad, Marienbad, Tarasp-Schuls, Franzensbad, Elster, and Bertrich.

(5) *Iron or chalybeate waters* are those in which an unusual proportion of this element is present, either in otherwise comparatively pure water or associated with other mineral matters. Thus, of comparatively pure chalybeate waters, there are those of Schwalbach, Spa, Brückenau, Schandau, Liebwert, Flinsberg, Freienwalde, Reccaro, Königswarth, Liebenstein, Altwasser, Alexishad, Muskau, Tunbridge Wells, and some of the springs at Harrogate; whilst of waters in which the iron is associated with a considerable quantity of other salts, there are those of Aratapak, Orezza, Pyrmont, Driburg, Rippoldsau, Griesbach, Antogost, Petersthal, Bocklet, St. Moritz, Reinerz, Godesberg, Cudowa, Imnan, and Santa Catarina.

(6) *Sulphur waters* are those containing appreciable quantities of either sulphuretted hydrogen or the sulphides of sodium, potassium, calcium, or magnesium. Some of the more important thermal sulphur waters are those of Eaux Chaudes, Cautelets, Saint Sauveur, Bagnès, Bagnères-de-Luchon, Ax, Escaldes, Le Vernet, Amélie-les-Bains, Uriège, Allevard, Aix-les-Bains, Aix-la-Chapelle, Baden (Austria), Baden (Switzerland), Lavey, Schinznach, Battaglia, and Abano in the Euganean Mountains, Panticosa, Mehadia, Helouan, near Cairo; whilst of cold sulphur springs there are those of Hilsen, Neundorf, Langenbrücken, Weilbach, Meisberg, Reutlingen, Engheim, Challes, Stachelberg, Hemstich, Gurnigel, some of the Harrogate springs, Llandrindod, Bulth, Moffat, Strathpeffer, Llandudnew.

(7) *Earthy and calcareous waters* are characterised by the presence of large proportions of calcium carbonate and sulphate, and magnesium carbonate. Some of the more important are found at Wildungen, Lipp Springs, Weissenburg, Contrexéville, Bagnères-de-Bigorre, St. Arnaud, Crausac, whilst the table waters of Couzan, St. Galmier, and Taunus are of the same character.

8. *Sea water*.—The ocean is a great evaporating-basin, which is constantly receiving waters, more or less impure, in the shape of rivers, whilst at the same time it is constantly losing pure water in the form of vapour, the impurities remaining behind and imparting to the sea its well-known saline character. This also distinguishes all lakes which are devoid of outlet, like the Dead Sea, Caspian, Aral, Great Salt Lake Utah, &c., in which the same process of concentration by evaporation is going on. As will be seen from the table on the next page, the composition of the ocean varies considerably in different places and at different depths, whilst land-locked seas, like the Mediterranean, Black Sea, and Baltic, present even still greater differences.

Thus in the vicinity of the poles the proportion of salt is less than near the equator; similarly, land-locked seas, such as the Black Sea and Baltic, which receive large rivers are salt; whilst the Mediterranean in most places is more salt than the great oceans. Of salt lakes the Dead Sea is far more and the Caspian far less salt than the oceans. In addition to sodium chloride, the principal substances present in sea water are the sulphates and carbonates of calcium and magnesium, and salts of potassium, whilst in very minute quantities there are found also a number of others, amongst which may be mentioned bromides, iodides and fluorides, silica, phosphoric and nitric acids, iron, silver, gold, copper, lead, arsenic, zinc, cobalt, nickel, lithium, rubidium, and caesium.

The volume of gas dissolved in sea water is, according to Hunter (Chem. Soc. Trans. 1870, 20), only from 2·2 to 3·5 vols. in 100 vols. of water.

	CO ₂	O	N
	cent.	per cent.	per cent.
2·2 vols. consisted of	28·62	21·94	49·44
3·5 " "	48·28	17·22	34·50

A very extensive examination of the composition of sea water was made in connection with the voyage of H.M.S. *Challenger*, and the elaborate report prepared thereon by Dittmar should be consulted for detailed information on this subject. From 77 complete analyses, the following numbers for the average composition of ocean-water salts are calculated:—

Average composition of ocean-water salts, in parts per 100 of total salts (Dittmar).

Chlorine	55·232
Bromine	0·1834
Sulphuric acid (SO ₃)	6·410
Carbonic acid (CO ₂)	0·152

The salinity of the ocean, expressed in parts of total salts per 1000 parts of sea-water, was found to vary between the following limits: Minimum (from the southern part of the Indian Ocean, south of 66° lat.), 33.01; maximum (from the middle of the North Atlantic, at about 23° lat.), 37.37.

As regards the carbon dioxide in sea water, Dittmar comes to the following conclusions:

(1) Free carbonic acid in sea water is the exception; as a rule, the carbonic acid is less than the proportion corresponding to bicarbonate. (2) In surface waters the proportion of carbonic acid increases when the temperature falls, and vice versa. (3) Within equal ranges of temperature it seems to be lower in the surface water of the Pacific than it is in the surface water of the Atlantic Ocean.

Drinking Water. It has long been known that the palate is by no means a safe guide in the choice of drinking water, for although unpalatable waters are obviously unsuitable for drinking, palatable waters may contain materials capable of doing serious injury. It is now established beyond question that the diseases termed 'zymotic' are due to minute forms of life known as micro-organisms, and in a number of cases the specific forms responsible for such diseases have been discovered, identified, and studied. Of zymotic diseases there are two—Asiatic Cholera and Typhoid Fever—which are with certainty known to be propagated by drinking water, and in the case of these two diseases authorities are agreed as to the particular organisms to which they are due. The propagation unquestionably takes place through the excreta of persons suffering from these diseases gaining access to water which is afterwards used for drinking, whilst water contaminated with the sewage of healthy persons is generally believed to be capable of producing diarrhoea and other minor disturbances in those drinking it.

In selecting water for drinking purposes it is necessary, therefore, in the first instance, to make a careful inquiry as to the possibility of the water having been in contact with refuse animal matters, and if possible all waters open to such suspicion should be discarded. For the same reason it is of the first importance in the examination of water to discover what evidence, if any, there is of the water having been in contact with such refuse substances. In the present state of knowledge this is a difficult matter, as, although the results of chemical analysis frequently point to such contamination when on a sufficiently large scale, it is occasionally and indeed generally impossible to prove the negative. The bacteriological examination, on the other hand, is of extreme delicacy, but, inasmuch as we have at present no means of ascertaining whether the bacteria indicative of faecal contamination are derived from man or from the lower animals, the results obtained by this means, also, are often of restricted value from a hygienic point of view. It becomes, therefore, of the greater importance to make a thorough inspection of the source and to trace out the further history of the water, for unless this be done the results of the scientific examination may often receive an erroneous interpretation. As, however, it is comparatively rarely

that natural waters are to be met with which are absolutely above suspicion of any contamination with refuse animal matters, it is generally necessary to be satisfied with relative purity, and thus the examination, chemical and biological, of drinking waters becomes a matter of the highest importance and utility. The natural waters which can lay claim to the greatest degree of safety for drinking purposes are of two kinds.

1. Unpolluted surface waters (generally upland waters).

2. Naturally filtered waters (spring and deep well waters).

In the first case the waters, both by inspection and analysis, must bear no evidence of animal contamination, and this is generally possible in the case of waters which are fit at altitudes above that of human habitations. A number of our large towns are supplied with water of this kind, although the gathering grounds do in most cases contain some houses so that absolute freedom from sewage contamination cannot generally be guaranteed. In the table on p. 381 the chemical composition of some of these upland surface water supplies is recorded.

The majority of upland surface waters are either very soft or of only very moderate hardness, and as in many of these towns extensive manufactures are carried on, these supplies are not only valued because of their safety for drinking, but also on account of their fitness for industrial purposes. It should always be remembered, however, that these surface waters may at times receive more or less sewage contamination, and that the ova of animal parasites derived from the cattle grazing on the gathering grounds may also be present, and that, therefore, to reduce these sources of danger to a minimum, it is highly desirable that such waters should be subjected to prolonged storage in reservoirs, followed by careful filtration through sand before delivery to the consumer.

In the second class of water its original purity is a matter of secondary consequence, the guarantee of safety resting upon the exhaustive process of filtration which the water has undergone in passing through porous strata of the earth's crust. This filtration effects, on the one hand, the more or less complete chemical purification of the water from organic substances, and, on the other hand, the mechanical removal of organised matters, such as bacteria and animal parasites. The most perfectly filtered waters of this kind are those obtained from springs and from deep wells, and, again, many of our towns are supplied with water of this kind—more especially from the Chalk, Greensand, Oolite, and New Red Sandstone formations, which constitute efficient filter beds. In the table on p. 382 is recorded the chemical composition of the water supplied to some of our towns from such sources.

Of other forms of drinking water we have river waters and shallow-well waters, upon both of which a very large portion of the population is dependent for domestic supply. Both of these classes of water are open to grave objections, and nearly all the best authenticated cases of the propagation of cholera and typhoid through drinking water have been traced to

shallow wells. There are, however, many potent influences tending to remove bacteria from water which, on a *priori* reasoning, would have been regarded as almost, if not wholly, inoperative. These causes are mainly the process of devitalisation which pathogenic bacteria undergo in natural, and more especially in surface waters, and the resistance offered by even a comparatively small thickness of soil or other porous material to the passage of micro-organisms. But although these causes are to be looked upon as tending to keep the evils which can result from contaminated drinking water within narrower limits than might have been anticipated, still the possibility of their failure must be constantly kept in view, and they must not be allowed to check the endeavour to substitute unimpeachable for suspicious sources of supply.

Every effort should be made to exclude avoidable sources of contamination, to select the best water which the source affords, and to submit it to the most effective purification available. The improvements which can thus be brought about in water supplies obtained from suspicious sources is conspicuously exemplified in the case of the London supply derived from the rivers Thames and Lea. Here, on the one hand, increasing vigilance has been exercised by the Thames and Lea Conservancy Boards in the exclusion of dangerous matters from the rivers and their tributaries, whilst on the other hand the authorities supplying water have removed their intakes to points on these streams above the most serious pollutions; by increasing their storage capacity they are enabled not only to

avoid drawing from the rivers in times of flood, but also to bring about a great amelioration in the quality of the water during its sojourn in the reservoirs, whilst by improving their filtering appliances they secure a more perfect purification of the water which they have abstracted. Thus the water supplied to London to-day is both chemically and hygienically very different from what it was 60 years ago, although still derived from the same streams, which in the ordinary course of events would be more polluted now than they were then.

Importance to be attributed to various ingredients of drinking water.—It is only possible here to give a brief account of the importance which is usually attributed to the several ingredients which are commonly determined in the analysis of drinking waters.

Dissolved gases.—The gases present in ordinary drinking waters are those of the atmosphere—oxygen, nitrogen, and carbon dioxide. Their quantitative determination is of little or no significance in connection with the quality of the water for drinking, excepting that through the absence of dissolved gases a water has the flat taste of that which has been recently boiled. It is sometimes supposed that the absence of a due proportion of dissolved oxygen in water is an indication of the presence of decomposing organic substances, but this can only be the case with surface waters, as the very purest subterranean waters are almost entirely destitute of it. In the following table the proportion of the several dissolved gases in different kinds of water is recorded:—

Gases dissolved in 100 cub. ins. of water	Rain-water	Cumberland mountain water	Loch Katrine water	Thames water	Deep chalk well water
	cub. ins.	cub. ins.	cub. ins.	cub. ins.	cub. ins.
Nitrogen	1·308	1·424	1·731	1·325	1·944
Oxygen	0·637	0·726	0·704	0·588	0·028
Carbon dioxide	0·128	0·281	0·113	4·021	5·520
	2·073	2·431	2·548	5·934	7·492

The large proportion of dissolved carbon dioxide in the Thames and deep chalk well water is mainly combined with calcium carbonate as bicarbonate.

Total solid residue.—It is only rarely that the amount of the residue left by a water on evaporation affords any evidence of its fitness for drinking. As a general rule, it may be stated that waters which contain very small residues are probably pure and unpolluted, but on the other hand many waters of organic purity contain large proportions of mineral matter in solution. It is impossible to assign limits to the proportion of mineral matter which may be present in water without interfering with its fitness for drinking, more especially as opinion is divided as to the influence of the several constituents on health (*v. also Hardness of water*). Nearly all the best drinking waters in the United Kingdom yield less than 50 parts of solid residue per 100,000, and most of them very considerably less. The use of waters yielding much larger residues is generally avoided by the inconvenience which attends

their employment for general domestic purposes, in consequence of their unfitness for boilers and washing.

Organic matter.—As will be pointed out (under *Water analysis*), the accurate determination of the organic matter in water is attended with great difficulties, and none of the methods of analysis in use claims to effect more than a partial determination. Thus in the 'combustion process' the organic carbon and nitrogen are determined with more or less accuracy; in the alkaline permanganate process that portion of the organic nitrogen is discovered which is readily convertible into ammonia, whilst in the 'permanganate' or 'oxygen' process the proportion of permanganate destroyed by the organic matter is taken into account. Although it may be stated generally that the smaller the proportion of organic matter the more desirable is the water for drinking, of still greater importance is the determination of the origin of the organic matter present, whether animal or vegetable. The presence of vegetable matter is of comparatively little consequence

more especially as even small amounts interfere with the palatability of the water, what is known as a 'peaty taste' being imparted by any amount yielding much in excess of 0.2 part per 100,000 of organic carbon. Sometimes much light may be thrown on the origin of the organic matter in water by the proportion which the carbon and nitrogen exhibit towards each other, especially when this is considered in connection with the proportions of ammonia, nitrates, nitrites, and chlorine. Inasmuch as animal matter in general contains a much higher proportion of nitrogen to carbon than does vegetable matter, it follows that the higher the ratio of nitrogen to carbon in the organic matter present in a sample of water, the more probability is there, *ceteris paribus*, of its being derived from animal sources and *vice versa*. The possibility of such diagnosis, however, is considerably limited by the fact that in the oxidation of peaty matter the organic carbon disappears much more rapidly than the nitrogen; whilst, on the other hand, in the oxidation of animal matter there is conversely a tendency for the organic carbon to become concentrated, thus leading to a simulation of animal matter in the case of vegetable, and a simulation of vegetable matter in the case of animal substances after oxidation.

It is thus essential that the evidence afforded by the proportion of organic carbon to nitrogen should be supplemented by an inspection of the source, and by a consideration of the mineral nitrogenous ingredients—ammonia, nitrates, and nitrites—all of which are principally derived from the decomposition of animal matters.

Albuminoid ammonia.—The ammonia yielded on distillation with alkaline permanganate is so frequently made the only measure of the organic matter present in water that a few words are necessary to indicate what is the importance to be attached to the results obtained in this simple process. According to its author, the late Mr. Wanklyn, 'deep spring water is often so pure as not to yield 0.01 part of albuminoid ammonia per million; and unless mixed

with surface water does not yield so much as 0.05 part.' 'The filtered water supplied by water companies—no matter whether derived from a lake, from clean mountain streams, or from defiled rivers—yields from 0.05 to 0.10 part of albuminoid ammonia per million; and, indeed, if the filtration be efficient, approximates to 0.05.' 'When the filters are over-taxed, as happens in the rainy season and in the winter, water companies supply imperfectly-filtered water, in which as much as from 0.10 to 0.20 part of albuminoid ammonia is found.' This statement must be accepted with great reserve, for in the winter months such surface waters almost invariably contain a much larger proportion of organic matter than during the dry season, thus accounting for the increase in albuminoid ammonia quite irrespective of any over-taxing of the filters. On the other hand, the albuminoid ammonia is the chemical ingredient in water which is most affected by filtration. It would appear, therefore, that suspended particles of vegetable and animal matter, which are removed by sand filtration, are particularly productive of ammonia on distillation with alkaline manganate. In fact, the chemical between a water before and after sand is often only attested by the diminution of albuminoid ammonia yielded by the filtered water.

Oxygen or permanganate process.—The analytical value of measuring the proportion of organic matter in water by the amount of permanganate it is capable of decolorising is discussed in the section of this article on *Water analysis*, and it will be sufficient here to give some idea of how the results are to be interpreted. As in the case of the organic elements determined by combustion, it has here again been attempted to establish a scale of classification, which, however, must also be used with the greatest caution and in conjunction with the other analytical data, as well as with regard to the water's source and history. Thus the following artificial standards have been suggested:—

	Oxygen absorbed in three hours at room temperature from potassium permanganate by 100,000 parts of water	
	For Upland Surface Water	For other Water
Class I. Water of great organic purity . . .	0-0.1 part	0-0.05 part
" II. " medium " . . .	0.1-0.3 "	0.05-0.15 "
" III. " doubtful " . . .	0.3-0.4 "	0.15-0.2 "
" IV. Impure water . . .	above 0.4 "	above 0.2 "

It will be readily understood that a great drawback to this permanganate process consists in its not distinguishing between nitrogenous and non-nitrogenous organic matter. Hence it is very desirable that, if the combustion process cannot be resorted to, it should be supplemented by a determination of the 'albuminoid ammonia,' or of the Kjeldahl nitrogen (see p. 403).

Mineral nitrogen (ammonia, nitrates, and nitrites).—The importance of these ingredients is an indirect one. In themselves they in no influence the wholesomeness of

water; but, on the other hand, they are of consequence as indicating what the previous history of the water has been. Thus, in the ordinary process of decomposition to which organic matters are subjected in nature, the nitrogen is principally liberated in the form of ammonia, and this, by subsequent fermentative oxidation, may become converted into nitrites and nitrates. Moreover, owing to the far average richness in nitrogen of animal vegetable matters, it is evident that these primary and secondary products of decomposition

furnish valuable evidence as to the previous contact of water with nitrogenous, and more especially animal, substances. As a general rule, the presence of ammonia indicates a more recent contact with such matters than does that of nitrates or nitrites, although in the case of some deep subterranean waters it appears that the nitrates originally present in the water have undergone reduction to ammonia, and hence the latter in such cases must be regarded as evidence of a more remote character even than the nitrates themselves. Again, in the ordinary course of nitrification in nature the ammonia is wholly converted into nitrate, the preliminary oxidation to nitrite being rapidly passed over; but if water containing nitrates is brought in contact with organic matter, these nitrates become more or less reduced to nitrites through the agency of certain micro-organisms (P. F. Frankland, Chem. Soc. Trans. 1888, 373; Warington, *ibid.* 742), and hence the presence of nitrites generally constitutes evidence of contamination with organic matter subsequent to the original nitrification, rather than to the latter having been imperfect. The fact must also not be lost sight of that nitrates can be reduced by certain microbes in the presence of organic matter with elimination of the nitric nitrogen in the free state, or as oxides of nitrogen, and that a contamination of the nitrified water may thus lead to the more or less complete removal of the mineral nitrogen. The absence of nitrates may thus, under some circumstances, actually indicate contact with animal matter instead of freedom from it (Munro, Chem. Soc. Trans. 1886, 632).

It must also be remembered that, in the case of surface waters, the mineral nitrogen may undergo removal through being taken up as food by plant-life, and thus the evidence of previous contact with animal matters be destroyed.

As the hygienic significance of contact with animal matters consists in the possibility of the ingress of pathogenic microbes (which may at any time be present in sewage and similar animal refuse), it is obvious that the evidence of such previous contact afforded by the presence of mineral nitrogen in any excessive proportion must be viewed as serious, if the history of the water furnishes no guarantee that any such organised poisons which may have gained access would have been subsequently removed, whilst the evidence is of far less consequence, or may indeed become entirely negligible, if in the subsequent history of the water it has undergone processes of purification which practically preclude the possibility of such poisons being still present. Until the application of bacteriology to questions of water supply, it was not possible to ascertain the efficiency of processes of water purification in this respect. But we now know that the exhaustive filtration through porous strata which spring and deep well water has undergone practically guarantees the removal of any micro-organisms which may have been originally present; in the case of river and shallow well waters, on the other hand, the chance of such removal is much less, and hence in such waters the evidence afforded by mineral nitrogen of previous contact with animal matters must be viewed with suspicion, whilst

in the spring and deep well waters it may often be disregarded altogether.

Chlorine.—This element is invariably in a state of combination—generally as sodium chloride, and hence quite innocuous. Its determination in potable water, however, is of importance as often affording information as to whether the water has been in contact with refuse animal matters or not. In this respect it is often more useful than the mineral nitrogen, as, once present in water, it cannot by any natural processes be removed. Its diagnostic value is due to the fact that human urine contains 500 parts of chlorine, or 824 parts of common salt in 100,000 parts. It is, of course, inapplicable in the vicinity of the sea and of natural salt deposits. In British waters free from animal pollution the average proportion of chlorine may be taken as 1 part per 100,000; but it is subject to very great variations.

There are, however, many other refuse liquids besides sewage which contain large quantities of chlorides, such as the effluents from dye and bleach-works, tanneries, paper-mills, alkali-works, and especially tin-plate and galvanising works, the proportion being often far in excess of anything ever found in sewage.

In America much attention has been bestowed on the proportion of chlorine present in unpolluted water at different distances from the sea-board. The points at which such waters exhibit the same amount of chlorine are joined by lines termed 'isochlors,' and these isochlors are found to be roughly parallel to the coast-line. Any water submitted for examination is then remanded for further inquiries if it exhibits more chlorine than is normal for the isochlor upon which the source of the particular water is situated. This is an attempt to make the chlorine a measure of the sewage contamination past and present, in much the same way as the proportion of total combined nitrogen has been employed by others. It has the advantage over the latter, inasmuch as the chlorine is practically permanent whilst the nitrogen is removable in various ways; but, on the other hand, the chlorine is subject to great variations within a small area, according to local circumstances, more especially geological. The chlorine, moreover, only testifies to contamination by liquid, and not by solid, excrements, and in this respect also is of less general applicability than the total combined nitrogen.

Hardness.—This term is applied to those ingredients in water which react with soap and produce an insoluble 'curd,' the principal substances in question being the various salts of calcium and magnesium, which, entering into double decomposition with sodium stearate (hard soap) or potassium stearate (soft soap), give rise to calcium and magnesium stearates, both of which are insoluble bodies, and soluble salts of sodium or potassium. On this account the salts of calcium and magnesium are manifestly detrimental to the fitness of the water for washing. As regards the influence of these salts upon the quality of drinking water, opinion is divided. Some consider the presence of a certain proportion of these salts desirable as furnishing the materials necessary for bone-formation; others contend that if present in more than a moderate proportion, they tend to

same calcareous concretions in the system, whilst, lastly, others regard their presence or absence as immaterial from a hygienic point of view. Further, by some authorities the sulphates and chlorides of calcium and magnesium (the so-called 'permanent hardness') are regarded as more objectionable than the bicarbonates or 'temporary hardness.' Again, there are many who view the presence of the salts of magnesium with more suspicion than those of calcium, and, indeed, magnesian waters are very generally credited with the power of causing phosphatic calculi, goitre, and cretinism. On this account it has sometimes happened that waters which were otherwise of most unimpeachable quality have been discarded in consequence of their containing a few parts per 100,000 of magnesia. All these views concerning the influence of calcium and magnesium salts are, however, based upon very unsatisfactory evidence. The Rivers Pollution Commissioners, in prosecuting their inquiry into this subject, found that 'where the chief sanitary conditions prevail with tolerable uniformity, the rate of mortality is practically uninfluenced by the softness or hardness of the water supplied to the different towns, and the average rate of mortality in the different water divisions varies far less than the actual mortality in the different towns of the same division. They were of opinion that, whilst waters of excessive hardness may be productive of calculus and perhaps other diseases, soft and hard water, if equally free from deleterious organic substances, are equally wholesome.' The question of magnesia in drinking water has been discussed by the writer ('What is the Importance of Magnesia in Drinking Water,' P. F. Frankland, Transactions of the Internat. Congress of Hygiene and Demogr. London, 1891), from whose inquiry it appears that whilst the amount of magnesia in the water supplied to most large towns is very small—generally not more than 1-2 parts of MgO per 100,000—it is much larger than is generally supposed in the well-water consumed by such a large portion of the population. Thus in the case of fifty brewery waters from all parts of the kingdom, the average amount of magnesia (MgO) was 3.41 parts per 100,000. It must also be remembered that the geological formation richest in magnesia (the magnesian limestone) is only very slightly represented in this country, so that the proportions of magnesia met with in the dolomitic districts of the Continent must be much larger.

Until, therefore, a far more searching inquiry than hitherto has been made into the alleged effect of such waters upon health, it would appear undesirable that any importance should be attributed to such proportions of magnesia as the above in drinking waters which are otherwise of unimpeachable purity.

The effect of Clark's process on magnesian waters is noteworthy. As a general rule, the proportion of magnesia removed by the treatment with lime is small—much smaller than that of the lime removed; but it is particularly worthy of notice that in cases where caustic soda was used in conjunction with lime, as is frequently done in the softening of water for industrial purposes, the magnesia may be removed in a greater proportion than the lime,

and as a matter of fact magnesium hydroxide is less soluble even than calcium carbonate.

The hardness of water not unfrequently throws light upon its previous history, for the food of both man and animals is of necessity rich in lime, and nearly the whole of this is in adult life again found in the liquid and solid excreta; hence water obtained from soil which has been much polluted with animal matters always exhibits a large amount of permanent hardness.

PURIFICATION OF DRINKING WATER.

Inasmuch as the impurities are either suspended or dissolved, mineral or organic, and the organic either animate or inanimate, it follows that the subject of purification may be considered from different points of view, according to the particular class of impurities the removal of which is under discussion. Until recently all the more important processes of drinking water purification were filtration processes, those depending upon precipitation being more especially of importance in connection with water for industrial purposes (see p. 391). Now, however, methods of more or less sterilising water by means of hypochlorites, ozone, or ultra-violet light are sometimes being resorted to (see p. 417).

Purification of drinking water on large scale.—

All surface water is liable to turbidity, and in times of rain and flood the amount of suspended matter may become excessive. It is, therefore, desirable that all surface water, even that from upland sources, should be submitted to purification before distribution for domestic purposes. The purification of surface water is best initiated by permitting the water to remain at rest in storage reservoirs for some days or even weeks, the greater part of the suspended matter thus becoming precipitated, and some destruction even of the dissolved organic matter also taking place. During storage most important biological changes also take place (see later). The process of filtration resorted to on the large scale is almost invariably that through sand of different degrees of coarseness. This method was inaugurated by Simpson, the engineer to the Chelsea Company in 1829, and has since been adopted in an ever-increasing number of places all over the world. The filter beds, as usually constructed, are 10-16 ft. in depth, often upwards of an acre in area, made water-tight with masonry, concrete, or puddled-clay walls. On the bottom are collecting drains, upon which is placed a layer of broken stone about 6 ins. in thickness, following upon which are layers of coarse gravel, fine gravel, and uppermost a stratum of fine sand, 1-4 ft. in thickness. The water is kept at a depth of 1-4 ft. above the surface of the fine sand, the rate of filtration varying in different works. For construction and cost of filtration plant, see Donald Chisholm, *Modern Methods of Water Purification*, London, 1911, 125. The greater part of the suspended impurities is retained in the downward passage of the water by the first few inches of fine sand, and sooner or later, sometimes in the course of a few weeks, causes the clogging of the filter. When the rate of filtration is too much retarded for practical purposes, the

surface of the sand is removed, after which the filtration can be continued until the filter is again choked, when the surface is again scraped off, the process being repeated until the stratum of sand becomes too thin to be efficient, after which the original thickness of the sand-layer is restored by means of washed sand. The sand scraped off is generally thoroughly washed, allowed to dry, and then used again. The particulars for the several sections of the Metropolitan supply, shown below, will serve to illustrate the method of working.

Besides the filter beds just described, some of the works drawing from the Thames are now using an auxiliary process of filtration through the natural gravel beds which form the banks of the Thames at Hampton. These gravel beds are at all times full of water, which forms, as it were, an underground river, and underground pipes are laid in this gravel and connected with a pumping well in order to utilise this water, which is always clear and bright in consequence of the natural filtration which it has undergone. In order to increase the supply of this underground water the gravel bed is flooded with water directly from the Thames, for which purpose a second series of perforated pipes are laid parallel to the first and placed at a distance of about 30 yards from them. This second series of pipes is placed in direct communication with the Thames, but at the point of ingress is

placed a small vertical sand filter to arrest the coarser impurities.

Such sand filters, although very efficient in removing the suspended matter, have comparatively little action upon that which is dissolved. Thus the following figures exhibit the composition of the York water supply, before and after filtration through sand:—

(Results of Analysis expressed in parts per 100,000.)

	Before filtration	After filtration
Total solid matters	28.40	26.20
Organic carbon	0.123	0.119
Organic nitrogen	0.023	0.022
Ammonia	0	0
Nitrogen as nitrates and nitrites	0.077	0.089
Chlorine	1.6	1.6
Temporary hardness	11.5	10.9
Permanent hardness	7.1	7.1
Total hardness	18.6	18.0
Micro-organisms (colonies yielded by 1 c.c. of water on cultivation with gela- tin-peptone)	31,200	122

It was formerly supposed that such sand filtration could have little or no effect in removing the micro-organisms present in water, as the interstitial spaces between the grains of sand are so large in comparison with the minute dimensions of the microbes. It was first shown

METROPOLITAN WATER SUPPLY, JANUARY, 1911.

Monthly Reports by Metropolitan Water Examiner to Local Government Board.

by Koch in Germany, and by the writer in this country, that nearly all the microbes in water may be removed by the sand-filters (Koch, Bericht der Deputat. f. die Verwaltung der Canalisationenwerke, Berlin, 1883; P. F. Frankland, Proc. Roy. Soc. 1885; Proc. Inst. Civ. Engineers, 1885-6; J. Soc. Chem. Ind. 1885, 1887), and this result has been since confirmed by many other investigators.

It was, in fact, supposed by Koch and his pupils that the sand filtration really removed all the microbes originally present in the water, and that those always found in the filtered water had gained access subsequent to filtration. The writer had, however, from the first shown that

London water supply there was an obvious relationship between the numbers of microbes in the unfiltered and filtered waters respectively necessitating the conclusion, therefore, that the sand filters can only be credited with removing a portion and not the whole of the micro-organisms present. This is sufficiently conspicuous from the tables on next page, which record some of the writer's results obtained with the London water supply during the year 1886, and reported to the Local Government Board (P. F. Frankland J. Soc. Chem. Ind. 1886). The unfiltered Thames water was in every case collected near the intakes of the several water companies at Hampton, and the filtered water from the mains of the Chelsea, West Middlesex, Southwark

Grand Junction, and Lambeth Companies respectively.

C. Fraenkel and Piefke (Zeitsch. Hygiene, 8, 1890, 1-40) subsequently demonstrated by direct experiment that particular species of bacteria purposely introduced into the unfiltered, were still present, although in greatly diminished numbers, in the filtered water.

The wonderful efficiency of these sand filters in removing microbes was at first very difficult to account for, but it is now recognised to depend upon the impervious nature of the slimy deposit which forms upon the surface of the sand, and until such a coating has been established the filter has but little effect in removing micro-organisms (Piefke, Aphorismen über Wasser-versorgung, Zeitsch. Hygiene, 7, 1889, 115-179). This slimy deposit consists not only of silt, mud, and colloidal matter, but also of a multitude of living forms—diatoms, green and blue algae, innumerable bacteria, fungi, and protozoa. Many of these forms actually feed on

bacteria. The rate at which filtration is carried on is also a most important factor, the more rapid the rate the less efficient being the purification (P. F. Frankland, Proc. Inst. Civ. Engineers, 1885-6). Although the removal of bacteria is not attributable to the sand particles as such, there is abundant evidence that the finer the sand and the greater its depth the more efficient is the filtration. This is doubtless due to a better support being given to the filtering skin, and to the finer and thicker layer of sand regulating the passage of water through the medium, whilst the water is also brought into more intimate and prolonged contact with the colloidal matter with which the sand of a matured filter is clothed. The statistics of the London water-works show that the cost of filtration as carried out by them averages about 0.6d. per 1000 gallons.

In countries liable to extreme cold—indeed, even in cold winters in this country—the process of sand filtration offers great difficulties, in consequence of the freezing of the filters; and this

has, in Berlin, been guarded against by the construction of a number of covered filter-beds. In the United States, where the same difficulty exists, the Hyatt system of filtration has been employed on a considerable scale. In this the water is first treated with a minute quantity of alum (about $\frac{1}{2}$ grain per gallon), after which it passes through a steel filtering chamber, consisting of a vertical cylinder the diameter of which is nearly twice its height. This cylinder is divided by a horizontal diaphragm, capable of withstanding the hydrostatic pressure necessary for rapid filtration. The lower half contains the filtering material, composed of 2 parts coke and 3 parts sand. The upper part of the cylinder is used for washing the filtering material, which at regular intervals is transferred into it in a state of violent agitation by hydraulic currents, the impurities flowing away through pipes situated near the top of the cylinder. In the process of filtration the water is admitted through pipes to the upper part of the lower section of the cylinder, and it is drawn off through perforated cups, which permit the water, but not the sand, to pass. It is claimed that the efficiency of the system depends more upon the successful precipitation and entanglement of germ life by the coagulant alumina than upon any special merits of the filter (Potable Water, Floyd Davis, Iowa, U.S. 1891). The cost of maintenance is said to be only one-fifth of that entailed by filter beds.

In recent years the use of mechanical filters has been gaining ground in Great Britain also, the Jewell, Bell, and Candy filters being those most commonly employed (see *Modern Methods of Water Purification*, Don and Chisholm, London, 1911; see also *Bacteriology of water*, below). The Puech-Chabal system consists in submitting the water to successive processes of filtration, sometimes as many as six stages, beginning with coarser grades of gravel and ending with fine sand, being employed. It is specially suitable for very turbid waters, as the life of the fine sand filter is greatly prolonged. It has been used at Magdeburg and other places (see Don and Chisholm, *l.c.*).

Of other methods of drinking-water purification on the large scale the only one that need be mentioned is Anderson's. The method consists in passing the water slowly through revolving iron cylinders about two-thirds filled with iron borings. A small quantity of the iron continuously passes into solution, so that the water becomes impregnated with ferrous iron, which subsequently, when the water flows into a settling tank, is converted into the ferric state with precipitation, a large proportion of the organic matter in solution being removed in the process, whilst a very considerable diminution in the number of vital germs is also effected. After undergoing oxidation in the settling tank, the water is finally filtered through sand before distribution. It takes $3\frac{1}{2}$ mins. for the water to pass through the rotating cylinder, the entire process occupying about 6 hours (Anderson *Proc. Inst. Civ. Engineers*; *Engineering*, 39, 525). This process has been used on a large scale at Antwerp and Paris.

Purification of drinking water on the small scale.—The filtration of water on the small scale was already known to the ancients. Thus Pliny mentions a method in which water was clarified

passage through wool. An immense number of different materials have been employed during recent years, but space will only permit of the brief consideration of a few of the more important ones.

Animal charcoal is employed in a number of common household filters, and from the invaluable services which it yields in sugar-refining it was anticipated that it would be highly efficient as a water filter. Unlike sand, it not only acts upon the suspended matters, but also removes a considerable proportion of the dissolved organic matter, and even some of the temporary hardness. Unfortunately, however, its action is very transient, and it generally soon becomes the seat of numerous organic growths, which are favoured by the calcium phosphate it contains, and the filtered water is then often rendered more impure than the unfiltered.

Vegetable charcoal has but little effect on the dissolved organic matters, although if in a sufficiently fine state of division it is an excellent strainer for suspended impurities (see table below).

Bischof's spongy iron, obtained either by reduction of hematite or of roasted pyrites, has a remarkable power of removing dissolved organic matters, as well as temporary hardness and nitrates, and this power is far more permanent than that of animal charcoal. It was for some time also employed on the large scale, in conjunction with sand, at the Antwerp Waterworks. The effect of filtration through animal charcoal and spongy iron respectively is exhibited in the table below.

Since the recent great advances in bacteriological science, it has become evident that the removal of micro-organisms from drinking water is a matter of much greater importance than the removal of organic matter, and hence it is in respect of this property that the value of filters is now generally estimated. The writer has shown (*The Removal of Micro-Organisms from Water*, P. F. Frankland, *Proc. Roy. Soc.* 1885) that several substances—such as coke, wood-charcoal, spongy iron, &c.—in a sufficiently fine state of division are capable of entirely removing all microbes in water passed through a stratum of a few inches of these materials. This power, which is quite independent of any chemical action (thus in the case of coke and wood-charcoal there is little or no removal of dissolved organic matter), is, however, not maintained unless the materials are frequently renewed; and in the case of animal charcoal which has been in use for a short time (one month) the number of microbes was found to be far greater in the filtered than in the unfiltered water. The most conspicuous instance of biological, as opposed to chemical, filtration is furnished by Chamberland's unglazed porcelain filter, which entirely removes microbes, but has no chemical action whatever (see table on next page).

A number of household filters in actual use have been examined with regard to their power of removing microbes by Plagge (*Public Health Section of Germ. Assoc. of Naturalists and Physicians*, 1886), who divides them into six classes, according to the materials used: (1) carbon filters, (2) stone and sand filters, (3) spongy-iron filters, (4) paper filters, of various kinds, (5) porous earthenware filters (Chamberland), (6) asbestos filters (Dr. H. H. H. H.).

and Schirmer). The carbon filters were found not only to admit of the free transmission of microbes, but in some cases the numbers in the filtrate greatly exceeded those in the unfiltered water. Thus in one case 68 colonies were obtained from 1 c.c. of the unfiltered, and 12,000 from 1 c.c. of the filtered water. The stone and sand filters were all found to be worthless. The spongy-iron filter yielded the following results: unfiltered water, 38,000 colonies from 1 c.c.; filtered, 18,000–24,000 colonies from 1 c.c. The paper filters all yielded very unsatisfactory results; the earthenware and asbestos filters, on the other hand, gave in nearly every instance a filtrate practically free from microbes. (For par-

ticulars concerning the sterilising power of the Chamberland filter, see also Miquel, *Analyses Bactériologiques des Eaux*, Paris, 1891.) The principal drawback to these porous earthenware filters is the rapid diminution in the rate of filtration which they exhibit. More satisfactory in this respect are the Berkefeld filters, similarly constructed of burnt infusorial earth (Nordt-meyer, *Zeitsch. Hygiene*, 1891, 10, 145; Bitter, *ibid.* 155). Neither the Chamberland nor Berkefeld filters permanently yield sterile water, some of the bacteria in the unfiltered water sooner or later growing through the pores. It is, however, doubtful whether any of the ordinary pathogenic bacteria would do this, as none of them are

(Results of Analysis expressed in parts per 100,000.)

³ P. F. Frankland, *Proc. Roy. Soc.*, 1885, 390.

known actually to multiply extensively in ordinary drinking water (Kübler, *Zeitsch. Hygiene*, 1890, 10, 48).

W. E. Hall has described a simple apparatus for the extraction of micro-organisms from samples of water. The sample is collected in a small straining jar through which any quantity of water can be passed, and the organisms retained in a quantity of water convenient for carriage.

From this concentrated sample the organisms can be extracted by passing it through a filter paper about 1½ in. diameter placed over a small funnel attached to a vessel from which the air is extracted by means of an exhaustor consisting of a modified form of filter pump.

The organisms are finally washed off the filter paper by means of a wash bottle with about 2 c.c. of water in which the organisms can readily be examined in a stage trough or placed in small quantities on a compressor slide (*J. Soc. Chem. Ind.* 1924, 43, 280).

Purification of drinking water by distillation.—This is, of course, the most effectual mode of freeing water from all its impurities. It is

resorted to, on a considerable scale, at sea, both for steam and sailing vessels. (For description of forms of apparatus in actual use v. Fischer, *Technologie d. Wassers*, Brunswick, 1880, 201–208.) The insipid taste of the distilled water can be removed either by aëration, or by filtration through animal charcoal or other porous substances. Distilled water is also employed to some extent for the manufacture of aerated waters and for artificial ice.

Purification of drinking water by boiling.—The purification consists, of course, only in the destruction of living organisms present in the water, but this is from an hygienic point of view of the greatest importance. In its action it is far more reliable than any process of filtration, and should be invariably resorted to in the case of waters which bear any suspicion of sewage contamination. The rapid taste of the boiled water may be removed by passage through a filter, which, however, should be exclusively employed for this purpose and not for filtering unboiled water. A convenient form of apparatus for sterilising large quantities of water—e.g. for hospitals, barracks, &c.—is described by

WATER.

Miquel (*Mannuel d'Analyse bactériologique des Eaux*, Paris, 1891, 1893). The more extensive use of boiled instead of filtered water is one of the chief sanitary desiderata of the day. Although absolute sterility cannot be *guaranteed* by a few minutes' ebullition, yet the reduction in the number of microbes by this simple process is so great that it may be safely regarded as ample for practical purposes. Thus Miquel and Wada (*ibid.* 185) found in the case of the Ourcq-canal water of Paris:—

Temperature.	Bacteria in 1 c.c.
14°C.	460,800
50° for 10 minutes	600

100°	0.5
100° for 20 minutes	0.0

WATER FOR INDUSTRIAL PURPOSES.

Of the numerous industrial uses to which water is put, the most general and important is the raising of steam. The composition of the water supplied to steam-boilers is a matter of great consequence, as the use of unsuitable water may cause the corrosion of boiler-plates and the formation of deposits, which not only occasion a serious loss of heat but may also lead to most disastrous explosions (*v.* **BOILER INCORUSTATIONS AND DEPOSITS**).

Water for other industrial purposes.—(1) For *brewing*, see art. **BREWING**. For use in bakeries, the water should be in all respects of the same degree of purity as is demanded for drinking purposes.

(2) For the *textile industries* the character of the water employed is often of great consequence. Thus in bleaching and dyeing the presence of iron and manganese, even in very small quantities, is highly deleterious, giving rise to iron and manganese stains on the bleached goods, and causing spots and modifications in the shades of dyed materials. Hard water, again, involves the use of larger quantities of alkali and soap in the several operations of boiling, scouring, and milling, and the insoluble lime-soap is left adhering to the fibre, often preventing the subsequent application of mordant or dye. In those operations, again, in which dyed fabrics are soaped, the lime-soap often injures the brilliancy of the colour, whilst in other cases the earthy soaps precipitated on the fibre act as mordants, and attract the colouring matters on those parts of the goods where it is not wished to fix them. In general, hard water has the effect of dulling many colours, and if due to bicarbonates retards, or even prevents, the dyeing of such colours as require an acid bath (e.g. cochineal scarlet). In some cases hard water containing bicarbonates wastes the mordants by precipitation in the bath instead of on the fibre, whilst it is sometimes actually beneficial for the washing of goods which have been mordanted with basic mordants. Such water is unsuitable for the solution of many coal-tar colours—e.g. methyl violet—a portion of the latter being lost as a tarry precipitate, whilst the goods are often spotted. For dyeing with some colours—e.g. alizarin and logwood—the

presence of a certain amount of lime is almost indispensable; a pure water to which a known quantity of lime-salt has been added is, however, preferable to a naturally hard water, especially if the latter is of variable composition. Water containing alkaline carbonates is sometimes advantageous, e.g. in wool-scouring, and in those dyeing operations in which the addition of sodium carbonate is prescribed; but in mordanting, in the dyeing with many colours, and in the washing of dyed goods, it is often very prejudicial; in these cases it should be neutralised with sulphuric or acetic acid. Acid waters are generally highly injurious, and should be neutralised with sodium carbonate. Sulphuretted hydrogen in water is also very objectionable in many operations of dyeing, more especially in mordanting with metallic salts (*Hummel, Dyeing of Textile Fabrics*). For the manufacture of *paper*, water containing iron is highly objectionable, giving rise to stains, whilst the presence of hardness is objectionable in causing the decomposition of the rosin-soap.

(3) For *tanning*, pure water is also a desideratum. Water much contaminated with organic matter causes injury to the surface of the leather, and sometimes a corrosion from the flesh-side of the skin. Water containing carbonic acid, or the bicarbonates, or calcium and magnesium sulphates, causes the hides to swell, whilst the chlorides prevent the swelling, and hence sea-water cannot be employed for the purpose. Hard water occasions a less perfect utilisation of the tanning materials, and an excess of chlorides retards the tanning process and causes the leather to attract moisture; the presence of iron is not so objectionable as is commonly supposed (*Fischer, Das Wasser*, 49–51).

(4) In *sugar-refining* the sulphates and alkaline carbonates are more productive of molasses than the chlorides, whilst nitrates are specially objectionable, as they prevent the crystallisation of six times their weight of sugar (*Fischer, Technologie d. Wassers*, p. 286).

Purification of water for industrial purposes.

As already pointed out, some substances, although unobjectionable in drinking water, operate prejudicially when the water is employed for many industrial purposes, and numerous methods have been devised for removing these impurities or for counteracting their effects. But few methods of purification have found favour in actual practice, and to these alone will any attention be given here. The processes which have for their object the removal of matters in suspension and organic substances have been already described under *Purification of drinking water* (*v.* p. 386), whilst the processes intended for the improvement of industrial water supplies are chiefly directed to the removal of lime and magnesia salts in solution, which, as has been shown above, interferes with the success of so many industrial operations. This removal of lime and magnesia salts is frequently spoken of as 'water-softening,' in consequence of the water after such treatment requiring less soap when used for purposes.

Purification with lime (Clark's process).—This method of purification was first proposed by Clark, of Aberdeen, in 1841, and consists in the decomposition of calcium bicarbonate or 'temporary hardness' of water by the addition of a suitable quantity of slaked lime, according to the equation

Thus both the lime in solution as bicarbonate as well as that added in the form of hydroxide are precipitated as normal carbonate, which is almost insoluble in water. The calcium hydroxide is sometimes added in the form of milk of lime, sometimes in that of clear lime-water, but the latter is far preferable, as the quantity added can be more easily controlled and an excess avoided. The necessary quantity of calcium hydroxide is most easily ascertained by adding such an amount that, after thorough mixing, a small quantity of the water taken out yields a yellow or brown colour with a solution of silver nitrate, more water is then added, until, on similarly testing, no coloration with the silver nitrate is obtained. This test should invariably be resorted to even in the case of such waters as are of very constant composition, and which, therefore, admit of the lime being proportioned by experience, as otherwise an excess or deficiency of lime is nearly sure to result. In its original form the Clark process is carried out in large tanks in which the water can remain at perfect rest for about 16 hours, although by the use of a floating exit-pipe the clear surface water can often be drawn off after 2 or 3 hours, and before the whole of the precipitate has reached the bottom. This method has been most successfully employed on a large scale at the Colne Valley Waterworks, near Bushey, at Canterbury, Caterham, and many other places on a small scale. The 'temporary hardness' only is, of course, removed, and even this not completely, as under the most favourable circumstances a small proportion of calcium carbonate remains in solution, whilst in the case of waters containing magnesium bicarbonate the removal of the latter is generally far less complete. In addition to these bicarbonates, the salts of iron and much organic matter are also removed.

In order to obviate the large amount of storage capacity required for Clark's process, several modifications have been introduced, in which the precipitate formed by the treatment with lime is either removed by filtration or made to subside rapidly by artificial means. The most notable of these improved processes are the so-called 'Porter-Clark,' in which the precipitate is removed with a filter-press, and Gaillet and Huet's process, in which subsidence is promoted by causing the water to take a circuitous zig-zag and upward path after the addition of the lime. In this latter process both lime and caustic soda are frequently employed in conjunction as the softening agents; in this manner both 'temporary' and 'permanent' hardness can be, to a great extent, removed, thus:—

does not permit the description of a number of other water-softening apparatuses

which are now on the market, and which only differ from each other in the special mechanical devices for supplying the chemicals (milk of lime, lime water, sodium carbonate, or caustic soda, as the case may be) and for removing the deposit. The Arobbutt-Deeley process, however, possesses certain features of interest. In this the clarification of the treated water is accelerated by stirring it up with the sludge of calcium carbonate obtained in previous precipitations, this being effected by blowing in compressed air through perforated pipes. The subsequent sedimentation takes place very rapidly, and the clear water is drawn off from the surface by means of a floating arm. Further, the danger of subsequent deposition of calcium carbonate in the service pipes, which often occurs when an insufficient time is allowed for sedimentation, is avoided by injecting carbon dioxide (obtained from a coke-stove, the gas being scrubbed with limestone to remove sulphur compounds) into the clarified water as it is drawn from settling tank.

Magnesia has also been employed to a limited extent for softening instead of lime. Under these circumstances the following reactions may take place, especially if heat is applied:—

(Fischer, Chem. Technol. d. Wassers, Brunswick, 1880, 264).

The formation of magnesium chloride is obviously disadvantageous for boiler purposes.

A number of other processes of chemical purification have from time to time been suggested, but none of them have met with any great success. Thus attempts have been made to utilise the following reactions:

In the *Permutite* process, devised by Dr. Gans of Berlin, the water is softened by filtration through artificial zeolite (a hydrated silicate of alumina and soda) to which the name of *Permutite* has been given. The latter is made by fusing together silica or quartz, alumina or china-clay, and sodium carbonate. The fused mass is extracted with water, a crystalline body ($\text{SiO}_2 = 46$, $\text{Al}_2\text{O}_3 = 22$, $\text{Na}_2\text{O} = 13.6$, $\text{H}_2\text{O} = 18.4$ p.c.) being obtained. When waters containing calcium or magnesium salts are filtered through this material, the following reactions take place:—

It is claimed for this process that the whole of the hardness is removed and that the calcium or magnesium zeolite formed can be reconverted into the original permutite or sodium zeolite treatment with a strong

Gans uses a mang

WATER.

alkaline, and a higher oxide of manganese) for the removal of iron and manganese in water. This material can be regenerated by treatment with a solution of potassium or calcium permanganate. The manganese-permutite can also be employed for the sterilisation of water; the water is treated with permanganate in sufficient concentration to destroy bacteria, and, on subsequent filtration through manganese-permutite, the whole of the manganese is said to be retained by the filter. Calcium-permutite has been used for removing potash from molasses, lime passing into solution; the lime may be replaced by soda by passing through sodium-permutite. The plant and materials for the Permutite process can be obtained from 'Water Softeners, Ltd.,' Kingsway, London, W.C.

For the effect of softening processes on the bacteria in water, *v. p.* 417.

The action of water on lead, zinc, copper, and aluminium.—The action of water on these metals, and especially on lead, is of great importance in connection with the distribution and storage of water. The Romans employed leaden pipes, and Vitruvius and Galen were aware that some waters were thereby rendered deleterious. On the other hand, certain waters have so little action on lead that pipes of this material have been in use for upwards of 200 years without showing any trace of corrosion (Fischer, *Technologie d. Wassers*, 317). As a general rule, hard waters, and more especially those containing bicarbonates, do not act on lead; the greater number of active waters are soft, and generally entirely destitute of bicarbonates. The activity has been ascribed by different authorities to the presence or absence of a great variety of ingredients in the water—*e.g.* the presence of dissolved air (Yorke), ammonium nitrite (Medlock), ammonium carbonate (Böttcher). Some have contended that organic matters diminish the activity (Horsford), others that they increase it (Hofmann, Graham, Miller, and Noad). The latter authorities were of opinion also that the presence of dissolved oxygen and the absence of more than 3 vols. of carbon dioxide in 100 vols. of water are amongst the conditions necessary for the attack upon lead. It has also been contended that a minute proportion of calcium phosphate prevents a soft water from attacking lead (*Riv. Pollut. Commis.* 6th Rep. 224), whilst according to others, again, the protecting ingredient is silica (Crookes, Odling, and Tidy, *Report on the Action of Water on Lead*, London, 1886). In many cases the activity of the water is due to the presence of organic acids (Allen), this being doubtless a fruitful cause of moorland waters acting on lead. The activity of many waters is confined to new untarnished lead, whilst others continue to act, sometimes with increased vigour, on the old and tarnished metal (P. F. Frankland, *The Action of Water on Lead*, J. Soc. Chem. Ind. 1889, 241).

Numerous expedients have been resorted to in order to destroy this activity of some soft waters. When acidity is the presumable cause the most obvious remedy is the filtration of the water through finely-divided limestone; in practice, however, this is found to be only of temporary service, as the surfaces of the limestone become coated with a film which prevents their

being further acted on by the water. It has been found more effective to mix the water continuously with a milk of finely-divided calcium carbonate, and allowing this to subside before the water is distributed.

It is now generally admitted that the action of water on lead is of two different kinds. Of these the most obvious is that due to the acidity¹ of some waters; such acidity may be due to organic or even mineral acids, and can be determined by titration with appropriate indicators. Such acid waters have, in general, a continuous action on lead. The acidity can, of course, be neutralised by the addition of lime, finely-divided calcium carbonate, or most effectively by sodium carbonate. It was, however, shown many years ago by the writer that such neutralisation does not necessarily entirely stop the action of the water on lead, and that this is often only secured by adding a considerable excess of sodium carbonate. Similarly there are many natural waters, which, although slightly alkaline with small proportions of calcium bicarbonate, nevertheless act on lead. Such action of neutral or even slightly alkaline waters is now usually termed '*erosive*' as distinguished from the '*plumbosolvent*' action of acid waters. These remarkable phenomena have only received a satisfactory explanation since the recent advances in physical chemistry have illuminated the subject of chemical equilibrium.

This matter is very ably dealt with in an important paper by Paul, Ohlmüller, Heise, and Auerbach (*Arbeiten a. d. kais. Gesundheitsamte*, 1906, 23: *Untersuchung über die Beschaffenheit des zur Versorgung der Haupt- und Residenzstadt Dessau benutzten Wassers, insbesondere über dessen Bleilösungsfähigkeit*). The conclusions arrived at by these authors are:—

1. *Dissolved oxygen* is necessary for the solution of metallic lead in pure water. Experiments made with distilled water, which had been saturated with air freed from carbon dioxide, showed that nearly the whole of the oxygen (amounting to about 9 mgms. per 1 litre) was taken up presumably according to the equation:

The water, which was at 18°, took up about 115 mgms. of lead per 1 litre. By increasing the proportion of oxygen in the air used for saturating the water the amount of lead taken up was at first also increased (up to about 140 mgms. Pb per 1 litre), but this was followed by a sudden drop to an amount which remained practically constant (about 108 mgms. per 1 litre for about 14.5 mgms. O₂ dissolved in 1 litre water). This sudden drop is referred to the appearance of a precipitate (*solid phase*) preventing further supersaturation of the water with lead hydroxide. (The authors did not determine the exact composition of the solid phase, which may have been Pb(OH)₂, or more probably one of its anhydrides.)

2. *Free carbonic acid* diminishes the plumbosolvent effect of the simultaneously present dissolved oxygen. Thus, in an experiment with distilled water made to contain about 8 mgms. O₂ and 40 mgms. CO₂ in 1 litre, the amount of lead

¹ See a paper on 'The Acidity and Alkalinity of Natural Waters,' by James Walker and S. A. Kay (*J. Soc. Chem. Ind.* 1912, 31, 1073).

taken up was about 11 mgms. per 1 litre, or about $\frac{1}{10}$ of that dissolved when the same proportion of dissolved oxygen was present in the absence of carbonic acid. This diminished plumbosolvency is, of course, attributable to the formation of a more insoluble solid phase, viz. either PbCO_3 , or more probably some basic carbonate such as $2\text{PbCO}_3 \cdot \text{Pb(OH)}_2$.

3. *Sodium bicarbonate* in the absence of any appreciable quantity of free carbonic acid greatly reduces the plumbosolvency of water; thus in similar experiments, in which the same proportion (about 9 mgms. O_2 per 1 litre) of dissolved oxygen was retained, but along with 35 mgms. of NaHCO_3 per litre, the amount of lead taken up was only 0.6 mgm. per litre of water. This, again, is attributable to the diminished solubility of the solid phase in the solution of the sodium bicarbonate. The amount of lead taken up by the water is limited by the *solubility product*; thus a saturated solution of lead carbonate will contain a small concentration of PbCO_3 molecules, together with $\text{Pb}^{++} + \text{CO}_3^{--}$ ions, of which only the PbCO_3 -molecules are in direct equilibrium with the solid phase (precipitated lead carbonate). The concentration of the PbCO_3 molecules will always remain constant as long as there is any of the solid phase present, but this concentration is very small. The concentration of the ions, on the other hand, is determined by the dissociation equilibrium. Thus, representing the molecular concentrations of the respective bodies by the formulæ enclosed in brackets, we have—

$$[\text{Pb}^{++}] \times [\text{CO}_3^{--}] = k \times [\text{PbCO}_3]$$

in which k is a constant. But in saturated solutions, as already seen above, $[\text{PbCO}_3]$ is constant, therefore $k \times [\text{PbCO}_3]$ is also constant, and can be represented by S , which is termed the *solubility product*, thus—

$$[\text{Pb}^{++}] \times [\text{CO}_3^{--}] = S$$

$$\therefore [\text{Pb}^{++}] = \frac{S}{[\text{CO}_3^{--}]}$$

which obviously signifies that the concentration of the Pb^{++} -ions will be the smaller the greater the concentration of the CO_3^{--} -ions. (If the solid phase is a basic carbonate, then it can be shown that the concentration of the Pb^{++} -ions must be inversely proportional to the concentrations of the CO_3^{--} - and the OH^- -ions.)

In solutions of free carbonic acid the concentration of CO_3^{--} -ions is very small (because carbonic acid being a very weak acid is only very slightly dissociated into ions), whilst in solutions of NaHCO_3 the concentration of CO_3^{--} -ions is much greater, and, therefore, the concentration of the Pb^{++} -ions will be correspondingly diminished, or, in other words, a much smaller proportion of lead will pass into solution. (It should be mentioned that the phenomena may be complicated by the circumstance that the nature of the solid phase may be different according as the metallic lead is placed in contact with a solution of free carbonic acid or bicarbonate respectively.)

4. The simultaneous presence of free carbonic acid and sodium bicarbonate leads to the following considerations:—

further $\text{H}_2\text{CO}_3 \rightleftharpoons \text{H}^+ + \text{HCO}_3^-$, whilst to a much less extent $\text{HCO}_3^- \rightleftharpoons \text{H}^+ + \text{CO}_3^{--}$. These dissociations are expressed by the equations

$$(1) [\text{H}^+] \times [\text{HCO}_3^-] = k_1 \times [\text{H}_2\text{CO}_3]$$

$$(2) [\text{H}^+] \times [\text{CO}_3^{--}] = k_2 \times [\text{HCO}_3^-]$$

in which the values

$$k_1 = 3.04 \times 10^{-7}$$

$$k_2 = 1.3 \times 10^{-11}$$

are known (J. Walker and W. Cormack, Chem. Soc. Trans. 1900, 77, 5; Bodländer, Zeitsch. physikal. Chem. 1900, 35, 23).

From equation (2)

$$[\text{CO}_3^{--}] = k_2 \times \frac{[\text{HCO}_3^-]}{[\text{H}^+]}$$

and combining this with equation (1) we have

$$[\text{CO}_3^{--}] = \frac{k_2}{k_1} \times \frac{[\text{HCO}_3^-]^2}{[\text{H}_2\text{CO}_3]}$$

but with PbCO_3 as solid phase we had

$$[\text{Pb}^{++}] = \frac{S}{[\text{CO}_3^{--}]}$$

which can, therefore, be written

$$\text{Pb}^{++} = \frac{S \times k_1}{k_2} \times \frac{[\text{H}_2\text{CO}_3]}{[\text{HCO}_3^-]^2}$$

But, inasmuch as free carbonic acid is very little, and sodium bicarbonate very much dissociated, the value of $[\text{H}_2\text{CO}_3]$ may be taken as proportional to the molecular concentration of the free carbonic acid, and $[\text{HCO}_3^-]$ to that of the sodium bicarbonate, and thus the concentration of the Pb^{++} -ions will be directly proportional to that of the free carbonic acid, and inversely proportional to the square of that of the sodium bicarbonate.

This important theoretical deduction was experimentally verified by placing lead in contact with water containing 8.3 mgms. O_2 , 35.3 mgms. NaHCO_3 , and about 33 mgms. CO_2 per 1 litre, with the result that the amount of lead in solution was found to be about 1 mgm. per 1 litre, and thus slightly but distinctly greater than in the previous experiment in which there was no free carbonic acid present, and in which 0.6 mgm. Pb per 1 litre was taken up by the water.

In ordinary natural waters the phenomena are complicated by the simultaneous presence of other salts, especially chlorides and sulphates. Both PbCl_2 and PbSO_4 are considerably more soluble than the carbonate. On adding 71 mgms. Na_2SO_4 per 1 litre to the last artificial water mentioned above, it was found that the proportion of lead taken up was about tripled, being about 3 mgms. per litre. This increase must, of course, depend on the presence of PbSO_4 molecules in solution, and not on an increase in the concentration of the Pb^{++} -ions, which it was shown was already fixed by the concentrations of the carbonic acid and bicarbonate. Now by removing some of the free carbonic acid (e.g. by adding Na_2CO_3) the concentration of the Pb^{++} -ions will be diminished, and this will have the effect of also diminishing the amount of lead in solution due to the solubility of the PbSO_4 , for the amount of undissociated PbCO_3 is dependent on the concentration of the Pb^{++} -ions, and if the latter be, through any cause,

WATER.

diminished, the amount of undissociated PbSO_4 must be diminished also, with the result that the total amount of lead passing into solution will be less. This was experimentally verified by using the same artificial water as in the last-mentioned experiment, excepting that by the addition of Na_2CO_3 the free carbonic acid was reduced to about 9.5 mgms. CO_2 per litre, and the NaHCO_3 consequently raised to about 128 mgms. per litre, with the result that the lead taken up amounted to only 1.3 mgm. per litre of water.

Experience has also shown that some waters act powerfully on lead when the pipes are charged intermittently, whilst the action becomes very much diminished if they are kept under constant pressure. The effect of pressure on the activity ought, therefore, always to be specially determined (P. F. Frankland, *J. Soc. Chem. Ind.*

In investigating the action of water on lead, the water should either be put in contact with strips of the metal or placed in leaden pipes for a definite period of time, after which it should be removed and tested for lead both in solution and suspension, fresh portions of the water under examination are then placed in contact with the metal and again tested after a definite interval of time, this procedure being repeated a number of times. Thus it is often found that a water has a considerable initial action on the metal, but as the latter becomes coated with deposit, the action moderates and may practically cease altogether. Some waters, on the other hand, act continuously on the metal.

Some polluted waters have a very strong and continuous action on lead (Riv. Pollut. Commiss. 6th Rep. 226), and in such cases the obvious remedy is the abandonment of the source.

It is worthy of note that hot water generally acts much more violently on lead than cold, and further that the lead dissolved in water is entirely removed by passage through any of the numerous forms of animal charcoal filters.

As regards the quantity of lead in water from which danger to health is to be apprehended, it is now generally admitted that water containing anything above one-twentieth grain of lead per gallon, or 0.07 part per 100,000, may, by continued use, produce mischief.

Of the action of water on zinc but little is known beyond the fact that many waters do act on it, and that it is therefore not to be recommended for the construction of cisterns, &c., in which drinking water is to be stored. The solution of the zinc takes place with special facility if metallic iron is also in contact with it (Heaton, *Chem. News*, 49, 85; P. F. Frankland, *ibid.* 115; Stevenson, *ibid.* 107).

Copper appears to be continuously acted on by water, especially if simultaneously in contact with air, and hence should not be used in connection with drinking water.

The action of water and other liquids on aluminium is now a matter of some importance owing to its use for domestic and industrial purposes (see *An Investigation of Aluminium, with Special Reference to its Suitability for the Construction of Brewery Plant*, A. C. Chapman, *J. Inst. Brewing*, 1911). Although acted on by moist air the layer of oxide exerts a marked protection to further attack; alkalis and alkali

chlorides increase the tendency to corrosion. Chapman considers that it may be safely used for the construction of brewing plant, especially fermenting tuns and vessels intended for the treatment of chilled and filtered beers.

THE CHEMICAL ANALYSIS OF WATER.

As the qualitative analysis of the ingredients of water is of no practical importance, and involves no special methods, the quantitative examination will alone be considered here. In order that the analysis may be of any value, especially for sanitary purposes, it is of the greatest importance that the samples should have been collected with care.

Suspended matter.—The suspended matter, if considerable in amount, should be separately determined, but if only present in minute quantity it is advisable to regard it as part of the dissolved matter, in which case it is necessary that the sample should be well shaken before taking out each portion for analysis, so that the suspended particles may be uniformly distributed. If it is decided to determine the suspended matter separately, the sample should be well shaken, and 250 or 500 c.c. measured out and passed through a filter previously dried at 100° and weighed. The matter on the filter is washed with distilled water, and dried at 100° until of constant weight. Some analysts prefer to dry at 105° , 110° , or even 120° , but in all cases the temperature should be specified. The filter and its contents are then incinerated in a coil of platinum wire and dropped into a weighed platinum crucible, gently ignited until free from organic matter, and then treated with a few drops of a solution of ammonium carbonate, and dried at 150° . The loss in weight represents organic matter and water of hydration. It is sometimes of importance to determine the proportion of carbon to nitrogen in the organic part of the suspended matter. For this purpose some of the suspended matter is collected on an ignited plug of asbestos or glass wool, transferred to a small flask, and boiled with 20 c.c. of sulphurous acid and some distilled water free from ammonia and organic matter, and then further treated, as in the determination of organic carbon and nitrogen, by the combustion process (p. 402). If the suspended matter has been thus separately determined, the remainder of the analysis should be performed on the water, after filtration through Swedish paper, rejecting the first 250 c.c. which pass through; or if the suspended matter completely settles on standing the clear water may be siphoned off. The suspended matter may, of course, in exceptional cases also have to be submitted to a complete mineral analysis, or examined for some special ingredient.

An ingenious method of determining minute traces of suspended matter has been devised by Dibdin (*Analyst*, 1896, 21, 2). In this method the volume of the moist suspended matter is measured in a capillary tube.

MATTERS IN SOLUTION.

Total solids.—250 or 500 c.c. of the water are evaporated to dryness in a watch-dish on a water- or steam-bath,

supported on a glass or porcelain, but not on a metallic ring. The dish and residue are then dried until constant at 100°, 105°, 110°, 120°, or even at 180°. The residue may be further utilised for the determination of nitrates and nitrites by the mercury method (*v. infra*).

Ammonia.—A measured volume of the water (varying from 100–1000 c.c., according to the proportion of ammonia present) is distilled in a capacious flask or retort connected with a Liebig's condenser, about 1 grm. of recently ignited sodium carbonate having been previously added. It is essential that the whole apparatus should have been carefully freed from ammonia immediately before use, which can be done by distilling some water in the apparatus until the distillate gives no reaction with Nessler solution. The remainder of the water in the flask or retort is then thrown away, and the measured quantity of the sample under examination introduced along with the sodium carbonate. The distillation should be carried on briskly, and the distillate collected in colourless glass cylinders of 50 c.c. capacity. If less than 500 c.c. has been used, this volume should be made up with distilled water free from ammonia before distillation. If the quantity of water has been well chosen, the whole of the ammonia will be found in the first three cylinders of the distillate, and in most cases it will all be contained in the first. The quantity of ammonia in each cylinder is estimated by adding 1 c.c. of Nessler solution, and comparing the coloration obtained with that similarly produced by known quantities of a standard solution of ammonium chloride, added to 50 c.c. of distilled water free from ammonia. The Nessler reaction is so delicate that by its means 1 part of NH_3 in 100,000,000 parts of water can be easily detected. The colour produced by more than 10–15 c.c. of a solution of NH_4Cl (containing 0.00001 grm. NH_3 per litre) is too deep for accurate comparison, and should one of the cylinders require more than this the determination must be repeated on a smaller volume of water. This may be generally avoided, however, by adding the Nessler solution to the second and third cylinders of distillate before the first, and if it is found that the second cylinder gives a colour requiring more than 5 c.c. of the above solution of ammonium chloride for its imitation the first cylinder should be diluted, and an aliquot part taken for testing with the Nessler reagent.

The Nessler solution is prepared by dissolving 62.5 grms. of potassium iodide in 250 c.c. of distilled water; set aside 10 c.c. of this, and run into the remainder a cold saturated solution of mercuric chloride until a permanent precipitate is formed, then add the above 10 c.c. of potassium iodide, which will cause its solution, after which very carefully add more of the mercuric chloride until a slight precipitate remains on stirring. Now add 150 grms. of potassium hydroxide dissolved in distilled water, and dilute the whole to 1000 c.c. After settling, decant the clear liquid into a bottle for use.

As the 'albuminoid ammonia' is commonly determined in one operation with the 'free' ammonia, the method of estimating the former will now be described, instead of considering it under the methods for determining organic matter, where it more properly belongs.

'Albuminoid ammonia' process.—Whilst the determination of the free ammonia is being proceeded with as above, the solution of alkaline permanganate must be prepared for this process, as it is required immediately the free ammonia has passed over. The volume of the alkaline permanganate (for preparation *v. below*) taken must be at least one-tenth of the volume of the sample being distilled for ammonia, and it should not exceed that volume unless the water contains a very large amount of organic matter. The alkaline permanganate taken is then diluted with four times its volume of distilled water, and boiled in a flask during the whole of the time that the distillation for free ammonia is going on as above, and when the latter is finished it is added to the water remaining in the distilling flask or retort (the whole volume in this must now be not less than 500 c.c.), and distillation is then continued until the distillate is free from ammonia. The distillate is collected and Nesslerised, as in the determination of free ammonia above. The ammonia thus evolved by distillation with alkaline permanganate is generally recorded as 'albuminoid ammonia' (*v. 403*). The alkaline permanganate solution is prepared by dissolving 200 grms. of potassium hydroxide and 8 grms. of pure potassium permanganate in 1100 c.c. of distilled water, then boiling the solution rapidly until concentrated to about 1000 c.c.

Chlorine.—(a) *Mohr's method.* 50 or 100 c.c. of water are treated with a few drops of a solution of potassium chromate, and a standard solution of silver nitrate is then run in from a burette until the precipitate becomes of a faint but distinctly red colour. The water must be well agitated after each addition of the nitrate, the reaction depending upon the decomposition of the red silver chromate by dissolved chlorides with formation of silver chloride and soluble chromate. As soon as the last trace of chloride is precipitated as silver chloride, the red colour of the silver chromate makes its appearance. By using a solution of silver nitrate containing 2.3944 grms. per litre, the number of c.c. employed gives at once (if 50 c.c. of water have been taken) the parts of Cl per 100,000, whilst if 100 c.c. of water are taken the silver nitrate solution should be of double this strength.

Mohr's method cannot be employed if the water is acid, and if this is the case a given volume of the water should be boiled with an excess of pure calcium carbonate (free from chlorides), filtered, the filtrate made up to known volume, and the chlorine determined in a part of this. In the presence of reducing substances, much organic matter, sulphuretted hydrogen, and sulphites, the method is also inapplicable, and in such cases it is desirable to determine the chlorine gravimetrically, which should also be done if the proportion of chlorine is large.

(b) *Volhard's method.* 50 or 100 c.c. of the water are treated with an excess of decinormal silver nitrate, the mixture being well agitated so as to cause the silver chloride to settle in flakes; the latter is filtered off and washed, and then to the filtrate about ten drops of a cold saturated solution of iron-alum are added, and subsequently enough strong nitric acid (free from nitrous acid) to remove the colour of the ferric

WATER.

salt. Decinormal ammonium thiocyanate is then added from a burette, stirring well all the time, until the liquid acquires a light yellow-brown colour, which remains permanent on leaving the liquid at rest for about 10 mins. By deducting the number of c.c.'s of thiocyanate from that of the silver nitrate added, the remaining silver nitrate indicates the proportion of chlorine present in the water. The advantage of this method consists in its being applicable to acid liquids. The method depends upon there being no formation of red ferric thiocyanate until the whole of the silver in solution has been precipitated as thiocyanate (*Annalen*, 180, 24).

Nitrogen as nitrates and nitrites.—A number of different methods have been devised for the determination of oxidised nitrogen; there are, however, only a few which have been largely adopted in practice, and such alone will be described here.

(a) *Crum's method.* This depends on the decomposition which nitrates and nitrites undergo when dissolved in strong sulphuric acid on being shaken up with mercury, and which leads to the evolution of the whole of the nitrogen as nitric oxide, the volume of which is then determined. The residue obtained in the estimation of the total solids (see p. 395) may be conveniently used for this determination also. This residue in the platinum or glass dish is repeatedly treated with a very small quantity of hot distilled water, which is brought into thorough contact with the residue by detaching the latter with a small glass rod covered with a piece of india-rubber. The aqueous extracts, which should in all not exceed about 10 c.c., are passed through a small filter and collected in a little beaker. This aqueous extract, containing all the soluble salts in the water residue, is evaporated nearly to dryness on a water-bath, after which it is dissolved again in a minimum quantity (1 or 2 c.c.) of water, and introduced into a Lunge nitrometer (*Ber.* 11, 434); the beaker is repeatedly rinsed with a few drops of hot water, and these rinsings added to the nitrometer. The beaker is then further rinsed with pure strong sulphuric acid (free from oxides of nitrogen), and this also is transferred to the nitrometer. About $1\frac{1}{2}$ volumes of sulphuric acid must in all be used to 1 volume of aqueous extract. If the water contains soluble carbonates there will be an evolution of carbon dioxide when the sulphuric acid mixes with the aqueous extract; the gas should be allowed to collect without shaking the tube, and should then be expelled. The contents of the nitrometer tube are now violently agitated with the mercury, and then in the course of a minute or so the evolution of nitric oxide will commence, and the agitation should be continued as long as any gas continues to come off. If the water contains a considerable quantity of chlorides some hydrogen chloride may have been given off with the nitric oxide, but this may be removed by admitting a little water into the nitrometer. When the gas has cooled to the temperature of the air, its volume is measured at atmospheric pressure. The determination is rendered more accurate, especially if the quantity of nitrates and nitrites is only small, by measuring the nitric oxide in Frankland's gas apparatus, in

which case the decomposition with mercury and sulphuric acid is effected in a small tube standing in a mercury trough, the evolved nitric oxide being then transferred to the gas apparatus (see Sutton's *Volumetric Analysis*). This method, which is by far the most convenient for ordinary water analysis, becomes inapplicable in the presence of very large quantities either of organic matter or of chlorides.

(b) *Methods of Schulze-Tiemann, and of Schlösing-Reichardt,* depend upon the decomposition of nitrates and nitrites by ferrous chloride and hydrochloric acid, and the measurement of the evolved nitric oxide. Of these methods, which closely resemble each other, the former, as the more convenient, need alone be considered here.

100–500 c.c. of the water are concentrated by evaporation to about 50 c.c., which are then introduced into a flask of about 150 c.c. capacity, provided with an india-rubber stopper, perforated by two narrow pieces of glass tubing, of which one (A) extends about an inch into the flask, and is constricted below, whilst the other (B) only just penetrates the stopper; the tube (B) is externally connected by means of a short piece of india-rubber tubing provided with a pinch-cock, with a delivery tube dipping into a trough containing 10 p.c. caustic soda solution previously boiled to expel air. The tube (A) is also connected with india-rubber and pinch-cock to another piece of glass tubing, which is allowed to hang vertically downwards. The water in the flask is vigorously boiled with the pinch-cocks open until the air is completely expelled by the steam, then the pinch-cock on (B) is closed whilst that on (A) is left open until the volume of water in the flask is reduced to about 10 c.c.; this pinch-cock is then also closed, and the flame removed from beneath the flask. The glass tube attached to (A) is carefully filled with water up to the pinch-cock; 15–20 c.c. of a saturated solution of ferrous chloride are introduced into the flask, in which there is now a partial vacuum, by siphoning from a small beaker through (A), the pinch-cock being temporarily opened, and about an equal quantity of strong hydrochloric acid is made to follow in the same manner into the flask. The flask is now carefully heated, and when the internal pressure rises the pinch-cock on (B) is opened, and the evolved gas allowed to pass through the delivery tube into a measuring tube filled with the 10 p.c. caustic soda solution standing in the trough. The heating of the flask is continued until the volume of gas in the measuring tube ceases to increase. The measuring tube is transferred to a tall glass cylinder full of water, and after the gas has acquired the temperature of the room the volume is measured at the atmospheric pressure, a correction being of course made for the tension of aqueous vapour.

This method is specially applicable to the case of water containing excessive quantities of organic matter and chlorides (*Ber.* 1873, 1041; Tiemann and Gärtner's *Untersuchung d. Wassers*, 170).

For Schlösing-Reichardt's method, see *Zeitsch. anal. Chem.* 1870, 24, or Tiemann and Gärtner's *Untersuch. d. Wassers*, 175.

(c) *The aluminium and zinc copper couple methods* depend upon the conversion by nascent

hydrogen of the oxidised nitrogen in the water into ammonia, and estimation of the latter by Nessler solution.

Aluminium method.—100 c.c. of the water are introduced into a flask together with 10 c.c. of caustic soda solution free from nitrates and nitrites, the mixture being boiled until it is reduced to about one-fourth of its volume. It is then diluted to about its original bulk with distilled water free from ammonia, and a piece of aluminium foil, about 2 ins. square and wrapped round a piece of glass rod, is dropped into the flask, which is then fitted with a stopper and small U-tube containing glass beads moistened with hydrochloric acid free from ammonia. After the evolution of hydrogen has continued for about 6 hours, the glass beads and washings of the U-tube are transferred to the liquid in the flask, the latter is then attached to a Liebig's condenser, and the ammonia determined by distillation and Nesslerising in the ordinary way (see p. 396). According to Tiemann and Gartner (*Untersuchung des Wassers*, 208), only the equivalent of 72–90 p.c. of the nitric acid is thus recovered as ammonia.

Zinc-copper couple method.—The residue obtained in the determination of 'total solids' is extracted with about 25 c.c. of hot distilled water, and this is boiled down with a fragment of recently-ignited pure lime about the size of a hemp-seed to one-fourth of its bulk. This liquid, together with the washings of the dish containing the residue, is transferred through a stoppered funnel into an eight-ounce Wurtz flask, attached to a Liebig's condenser, and containing the requisite amount of the zinc-copper couple. The distillation is carried on until the greater part of the water has passed over, after which hot distilled water is repeatedly run into the flask and the distillation continued until about 100 c.c. of distillate have been collected; the latter is then 'Nesslerised' in the ordinary way (Thorpe, *Chem. Soc. Trans.* 1873, 541). According to Tiemann and Gartner, from 88 to 95 p.c. of the nitric acid is thus obtained.

In the writer's laboratory the process is carried out as follows: A stoppered bottle (about 200 c.c. capacity) is loosely filled with strips of zinc, which, after cleaning with dilute sulphuric acid, are covered with copper sulphate solution (1 p.c.). The copper-coated strips are repeatedly washed with distilled water, and finally with the water under examination, care being taken not to detach the copper film. The bottle is then completely filled with the sample of water and a crystal of oxalic acid is added, and the bottle, loosely stoppered, is allowed to stand over night. A definite volume is withdrawn by means of a pipette, and this is distilled with a suitable volume of ammonia-free water in the ammonia apparatus as usual, a small quantity of ignited sodium carbonate being added. Before withdrawing the water from the bottle for distillation, a small quantity should be tested for nitrite to ensure that the reduction to ammonia is complete. Waters containing free or saline ammonia must have this distilled off before being placed in contact with the zinc-copper couple.

A rapid method of estimating nitrates in water is due to Harrow (*Chem. Soc. Trans.* 1891, 899), depending on the reduction to nitrite

by zinc-dust and estimation of the nitrous acid by sulphanilic acid and α -naphthylamine (Griess' test). This reagent is prepared by dissolving 1 grm. of α -naphthylamine, 1 grm. sulphanilic acid, and 25 c.c. strong hydrochloric acid in about 200 c.c. distilled water; boiling with a small quantity of animal charcoal, filter, and making up to 500 c.c. The process is conducted thus: 50 c.c. of the water are placed in a beaker of 100 c.c. capacity, and in three similar beakers 50 c.c. of three standard solutions of potassium nitrate, containing (1) 1.0 part N, (2) 0.1 part N, (3) 0.01 part N per 100,000; to each beaker 10 c.c. of the above test-solution are added, and afterwards a very small quantity (7–8 mg.) of zinc-dust. If nitrate is present in the water a pink colour appears, which must be compared with that yielded by the three standard solutions after 15 mins. This gives an approximate idea of the amount of nitrate present, whilst in order to obtain an accurate result the water must be diluted until the colour produced is almost identical with that given by one of the standards. The results appear to be accurate, but it is especially necessary to avoid the addition of large quantities of zinc-dust, which would decolorise the solution.

(d) *The indigo method* differs from those previously described in being a simple volumetric method depending upon the decolorising action of nitric acid on indigo solution. The results are only accurate when the greatest uniformity is preserved in the conditions under which the experiments are made—the process is, in fact, entirely empirical. It may be carried out as follows: 25 c.c. of the water are mixed with 50 c.c. of pure strong sulphuric acid; a dilute solution of indigo is then immediately added from a burette, shaking the whole time, until the solution acquires a bluish-green colour. In a second experiment nearly the whole volume of indigo which was found necessary in the first experiment is added at once, and the blue colour is then obtained by further small additions, and in this manner, by shortening the time taken in the titration, a more accurate result, generally higher than in the preliminary experiment, is obtained. The solution of indigo must be standardised under precisely similar conditions by means of a solution of potassium nitrate of known strength. The indigo solution should be chosen of such strength that 6–8 c.c. correspond to 0.001 grm. N_2O_5 ; and if 25 c.c. of the water contains more than 0.003–0.004 grm. N_2O_5 , it should be diluted before a final titration is made. The method is only suitable for use by an operator in continual practice (Warington, *Chem. Soc. Trans.* 1879, 578; *Water Analysis*, E. Frankland, 31). The results are too low if there is a large amount of organic matter in the water.

The methods described above do not distinguish between nitrous and nitric acids. Indeed, the indigo method is altogether unreliable in the presence of any notable proportion of nitrous acid, as is also Cram's method, should it be necessary to allow any carbon dioxide to escape before shaking with mercury (see p. 397). As nitrous acid is, however, generally only present in natural waters in minute traces, these difficulties do not frequently arise, and the

nitrous acid may be most conveniently estimated by colorimetric methods, of which there are several in vogue. Of these may be mentioned:

Table of hardness in parts per 100,000, 50 c.c. of water being used.

(a) *Preuss-Tiemann's method*, depending upon the production of Bismarck brown when an acid solution of a nitrite acts upon *m*-phenylenediamine. 100 c.c. of the water are placed in a colourless glass cylinder, 1 c.c. of dilute sulphuric acid (1 : 3) is added, and then 1 c.c. of solution of *m*-phenylenediamine (5 grms in 1000 c.c. distilled water, decolorised if necessary with animal charcoal); if the colour appears in less than 1 or 2 mins. the experiment must be repeated with a smaller quantity of water, in each case diluted, however, to 100 c.c. The coloration is then imitated under precisely similar conditions with a standard solution (the standardisation can be effected either by the potassium permanganate, or, better, by the urea method) of potassium or sodium nitrite. The final tint is not arrived at until the mixture in the glass cylinder has stood for 20-25 mins., which is the great drawback of the process (*see* also Warington, *The Detection of Nitric and Nitrous Acids*, Chem. News, 1885, 51, 39).

A preferable method (Zambelli, Chem. Soc. Abstr. 1887, 533) consists in adding to the water a few drops of a saturated solution of sulphanilic acid in dilute sulphuric acid, then a few drops of a saturated aqueous solution of phenol, after which the mixture is rendered alkaline with ammonia. The presence of nitrous acid is indicated by the appearance of a coloration, varying from faint yellow to intense reddish yellow, according to the quantity of nitrous acid present. The author claims that this method is capable of revealing the presence of 1 part of nitrous nitrogen in 40,000,000 parts of water. It has the great advantage that the reagents employed are permanent in solution.

For larger quantities of nitrous acid, as also for the standardisation of solutions of sodium and potassium nitrite, the urea method devised by the writer is to be recommended (Chem. Soc. Trans. 1888, 364).

Hardness.—The determination of the hardness of a water consists in empirically ascertaining the amount of soap which has to be destroyed by a given volume of the water before a lather can be obtained, and expressing this in terms of the amount of calcium carbonate which must be dissolved in the same volume of water to destroy the same amount of soap. Accurate results can only be obtained by preserving uniformity in the conditions of experiment.

50 c.c. of the water are measured into an 8-oz. stoppered bottle, which is then violently agitated and the air sucked out by means of a glass tube to remove any carbon dioxide which may be given off by the water. A standard solution of soap (*v. infra*) is then added in diminishing quantities not exceeding 0.5-0.10 c.c. at a time, even at first, violently shaking after each addition, until the froth produced remains unbroken over the surface for a period of 5 mins. when the bottle is placed at rest on its side. The quantity of calcium carbonate corresponding to the volume of soap solution employed can then be ascertained by reference to the empirical table

C.c. of soap solution	CaCO ₃ per 100,000	CaCO ₃ per 100,000	C.c. of soap solution	CaCO ₃ per 100,000

In performing the titration as above, the experienced operator is guided by the ear as well as by the eye, for the sound produced on shaking serves to indicate how the reaction between the hardening constituents of the water and the soap is progressing, for as this approaches completion the sound becomes softer, and when an excess of soap has been added the agitation is all but noiseless.

giving more than

16 c.c. of soap solution for the 50 c.c. of water, it is necessary to take a smaller volume of the water and dilute to 50 c.c. with boiled distilled water. The presence of magnesia salts is indicated in the soap test by the formation of a characteristic light curd, and also by the premature formation of a lather, which again disappears on the further addition of soap solution and shaking. If these signs are exhibited, only such a volume of water should be taken as, when diluted to 50 c.c., requires not more than 7 c.c. of the soap solution; indeed, it is a very good practice invariably to dilute waters so that not more than 7 or 8 c.c. of soap solution are required. In the presence of magnesia salts the results are always less accurate, and, unless great care is exercised, may become wide of the truth.

Permanent hardness.—The permanent hardness is most conveniently determined by taking a small flask with a *very short neck* (the Erlenmeyer shape is very suitable), and adding the water to it until a definite weight (e.g. 250 grms.) has been made up. The water is then maintained in gentle ebullition for exactly half-an-hour, and, after cooling, the weight is again made up to the original by the addition of boiled distilled water, the soap titration being then performed on a measured portion of this, as described above.

Some analysts prefer to take a given volume of water and restore the volume after boiling, then removing the precipitated carbonates of lime and magnesia by passing through a dry filter.

The *standard solution of soap* is prepared as follows. A cake of Castile soap is scraped with a knife, and about 7 grms. of the shavings are dissolved in 500 c.c. of a mixture of 2 vols. of methylated spirit with 1 vol. of distilled water. Filter off the insoluble matter, and dilute the soap solution with half its volume of water. A portion of this solution is then further carefully diluted with a mixture of 2 vols. methylated spirit and 1 vol. water until 7.8 c.c. are required to form a permanent lather with a mixture of 25 c.c. of the standard calcium chloride solution (prepared by dissolving 0.2 gm. of Iceland spar in dilute hydrochloric acid, and, after driving off excess of acid on the water-bath, making up to 1000 c.c. with distilled water) and 25 c.c. of distilled water.

Poisonous metals.—Of these the only ones which are of practical importance in water analysis are lead, zinc, copper, arsenic, and barium. As they are generally present in only very minute proportions, it is necessary to evaporate large volumes (5 litres and upwards) of water in order to obtain gravimetric determinations in the ordinary way; but the following special methods may be generally employed.

For *lead*, take 100 c.c. of the water, acidify with a few drops of acetic acid, and then add about 5 c.c. of a saturated solution of sulphuretted hydrogen. The colour produced is imitated by adding a known quantity of a standard solution of a lead salt to 100 c.c. of distilled water. Even such small proportions as 0.03 part Pb per 100,000 should invariably be recorded. (For the standard solution of lead, dissolve 0.1831 gm. crystallised normal lead acetate in 1000 c.c. distilled water; 1 c.c. = 0.0001 Pb.)

For *copper*, the same colorimetric method may be employed as for lead, using for comparison a solution of copper sulphate containing 0.0001 gm. Cu in 1 c.c. (0.3929 gm. crystallised copper sulphate per litre). In the absence of iron a very delicate colorimetric method may be employed, based upon the reaction between copper salts and potassium ferrocyanide, the water being acidified with hydrochloric acid, whilst in the presence of iron the blue coloration produced by ammonia may be used.

The presence of *zinc* is generally indicated by the gradual formation of a film of carbonate on the surface of the water when the latter is exposed to the air. Some of this film ignited on platinum foil should leave a residue, which is yellow when hot and white on cooling. The quantity of the zinc may be approximately determined, in the absence of other heavy metals, by acidifying 100 c.c. of the water with dilute hydrochloric acid, and then adding a solution of potassium ferrocyanide. The white turbidity produced is then compared with that obtained from a known quantity of a standard solution of a zinc salt (Snijders, Ber. 1878, 939).

Arsenic is best detected and estimated by Marsh's test; 500 c.c. of the water are rendered slightly alkaline with caustic soda or potash free from arsenic, and evaporated to dryness. The residue is extracted with strong hydrochloric acid, and the liquid introduced into a Marsh's apparatus. The gas is passed through a small U-tube containing pumice soaked in solution of lead acetate, and then through a piece of combustion tube constricted in the middle, where it is heated to redness. The passage of gas through the heated tube is continued for an hour, although nearly all the arsenic is liberated in 5 or 10 mins. The metallic ring formed is compared with a number of standard rings similarly obtained with known quantities of arsenic. A blank experiment must invariably be performed previously, to control the purity of the chemicals employed.

Barium may be detected and determined by concentrating a considerable volume of the water, acidifying with hydrochloric acid, and after filtering, if necessary, adding a solution of calcium sulphate. The barium sulphate precipitated is then collected and weighed in the ordinary manner.

Iron can generally be estimated colorimetrically by means of ferrocyanide or thiocyanate. Its determination is frequently of importance in waters used for industrial purposes.

In the ferrocyanide method, the water residue is dissolved in hydrochloric acid and diluted to 100 c.c. Of this 10 c.c. are transferred to a 100 c.c. cylinder; add 1 c.c. of strong nitric acid, dilute to 100 c.c., stir, and then add 1 c.c. of potassium ferrocyanide solution and mix well. The colour produced is compared with that obtained from a standard iron solution, but the same quantity of nitric acid must be present in each case (Sutton, Volum. Analys. 6th ed. 194; v. also Carter Bell, J. Soc. Chem. Ind. 8, 175).

In the thiocyanate method, two 100 c.c. cylinders are taken, and into each 5 c.c. of dilute hydrochloric acid (1 : 5) and 5 c.c. of dilute nitric acid (1 : 5), together with 15 c.c. of thiocyanate solution, are poured; then introduce a

measured volume of the liquid to be tested into the one cylinder, and after filling up both cylinders to the mark with distilled water, imitate the red colour obtained with the liquid under examination by running in a standard solution of iron from a burette into the other cylinder. In this way one part of iron is said to be recognisable in fifty millions of water (Thompson, Chem. Soc. Trans. 1885, 493).

Determination of organic matter.—A number of processes have been devised for the determination either of the whole or part of the organic substances present in water. Of those which lay claim to discovering the whole of these organic materials, none is entitled to any confidence, whilst even those which attempt to determine a part, or to indirectly obtain a comparative measure of the organic matter, are also open to objections on the score of accuracy. Only those methods more commonly in use by water analysts will be described here.

(1) *Methods depending on the reduction of potassium permanganate.*

(a) *Kubel's process.*—In this the reduction is effected in acid solution. 100 c.c. of the water are placed in a flask of about 300 c.c. capacity and treated with 5 c.c. dilute sulphuric acid (1 : 3), and then with such a quantity of standard dilute permanganate (equivalent to centinormal oxalic acid) that the liquid is of a strong red colour. The mixture is then boiled for 10 mins., and the excess of permanganate added must be such that the colour is not discharged in the operation. 10 c.c. of centinormal oxalic acid are now added, and into the resulting colourless liquid standard permanganate is then run until a faint red colour is obtained. The amount of oxygen consumed by the organic matter in the water can then be calculated.

(b) *Schulze's process.*—In this the reduction is commenced in an alkaline and completed in an acid solution. 100 c.c. of the water are placed in a flask of about 300 c.c. capacity, 0.5 c.c. caustic soda solution (1 : 2) are added, as well as 10–15 c.c. of standard dilute permanganate (equivalent to centinormal oxalic acid). The liquid is boiled for 10 mins., allowed to cool to 50° or 60°C. and then 5 c.c. of dilute sulphuric acid (1 : 3) and 10 c.c. of centinormal oxalic acid are added, the liquid being shaken and gently warmed until the colour has quite disappeared. Then the standard dilute permanganate is run in until a faint red colour, remaining permanent for at least 5 mins., is obtained. The oxygen consumed by the organic matter of the water is then calculated.

(c) *Forchhammer process.*—This resembles Kubel's method, inasmuch as the reduction of the permanganate is effected in an acid solution, but the temperature employed, instead of being defined, is that of the air of the laboratory.

Two flasks are carefully cleaned and into one 250 c.c. of the water, into the other 250 c.c. of distilled water, are introduced. To each 10 c.c. of dilute sulphuric acid (1 : 3) and 10 c.c. of standard permanganate (containing 0.395 gm. per litre or 0.001 gm. available oxygen in 10 c.c.) are added, and the mixture is allowed to stand for three hours. At the end of this time the excess of permanganate remaining is deter-

mined by adding two drops of potassium iodide (1 : 10) to each flask, and then running in a standard solution of sodium thiosulphate (1 gm. per litre) until the whole of the free iodine is removed, a drop of clear starch solution being added at the close of the operation. The amount of permanganate destroyed in the blank experiment must of course be deducted from that destroyed in the case of the water, and from the difference the oxygen consumed by the organic matter of the water can be calculated (Tidy, Chem. Soc. Trans. 1879, 66).

In this country it is now almost the invariable custom of water analysts to allow the acid permanganate to act for 4 hours at 80°F. (26.7°C.); Thorpe (Metropolitan Water Reports, 1904) has also used 1 hour at 122°F. (50°C.), under which conditions a larger amount of oxygen is consumed.

It must be pointed out that in these several methods depending on the reduction of permanganate, the results are only comparative for the same kind of organic matter, a given weight of organic carbon in different kinds of water consuming different quantities of oxygen from permanganate under the same conditions. Thus it has been found that for surface waters, such as those of the rivers Thames and Lea, by multiplying the oxygen consumed in the Forchhammer process by the factor 2.38, the proportion of organic carbon (as determined by combustion) is approximately obtained, whilst in the case of deep well water the factor which must be employed is 5.8 (Woodland Toms).

Again, all these methods are affected by the presence of nitrites, ferrous salts, and larger quantities of ammonia compounds, all of which exercise a reducing action on permanganate. By determining the nitrous acid, a correction can be made for this, whilst the ferrous can generally be converted into ferric iron by shaking up the water several times in a half-filled bottle previously to the oxidation with permanganate; and the error due to ammonium salts is so small that it can generally be neglected (even one part NH₃ per 100,000 has no appreciable reducing effect) (Preusse and Tiemann, Ber. 12, 1906).

(2) *Determination of organic carbon by oxidation of organic matter with potassium dichromate and sulphuric acid* (Wolff, Degener, and Herzfeld).—500–1000 c.c. of the water are introduced into a capacious retort, the neck of which is drawn out and bent downwards and is connected with a Liebig's condenser. This arrangement enables the retort to be turned upwards and the condenser downwards, thus preventing any loss by spurting during distillation, which is carried on until 250–700 c.c. (according to the volume of water employed) have passed over. The distillate is submitted to Kubel's method (*v. supra*) to ascertain whether any volatile organic matters are present. Alkaline waters should be saturated with carbon dioxide, and acid waters carefully neutralised with sodium carbonate before the above distillation. The water remaining in the retort is evaporated down to 15 c.c. in a glass dish on a water-bath, the access of dust being carefully avoided. This concentrated liquid is introduced into a flask of 250–300 c.c. capacity, and the dish and retort are rinsed with 10 c.c. of dilute sulphuric acid (1 : 3),

these rinsings also being added to the water in the flask. The decomposition of carbonates caused by the addition of this acid is completed by heating to 50°C. and shaking, and the evolved carbon dioxide completely displaced by air. After cooling the flask and its contents, 10 grms. of finely-powdered potassium dichromate are added, and the flask is then attached to the remainder of the apparatus. An india-rubber stopper with three holes is placed in the flask; through one hole passes a thermometer dipping into the liquid, through a second passes nearly to the bottom of the flask the tube of a bulb-funnel (A) provided with a stopcock, whilst through the third passes the bent tube of an inverted Liebig's condenser (B). The upper extremity of the condenser (B) is connected with two U-tubes (C and D) filled with fused calcium chloride, whilst between these is a third U-tube (E) containing coarsely-powdered antimony. Of these, C and D are intended to absorb the moisture passing the condenser, and the intermediate one, E, to retain any chlorine. Following on these tubes is a set of weighed potash-bulbs (F) for the absorption of carbon dioxide, and these bulbs are, of course, protected from ingress of moisture on the other side by means of a calcium chloride tube, which can be attached to an aspirator at the close of the experiment. The apparatus having been thus put together, 50-60 c.c. of diluted sulphuric acid (3:2) are gradually added through the stoppered funnel (A). During the first half-hour the temperature is kept at 50-55°C., whilst during the second half-hour it is gradually raised to boiling, which is maintained from 5-10 mins. The aspirator is then attached, the air which enters by the funnel (A) having been previously freed from carbon dioxide by bubbling through caustic potash. The increase in weight of the potash bulbs (F) gives the weight of carbon dioxide evolved, from which the carbon itself can be calculated (Ber. 1886, 2618; Tiemann-Gärtner, *Untersuch. d. Wassers*, 247).

For a somewhat similar method of determining organic carbon in which permanganate is used instead of dichromate, see Blair, *Organic Analysis of potable Waters*, Churchill, 1891, 83. The method appears worthy of more extended trial.

(3) *Determination of organic carbon and nitrogen by combustion.*—(a) *Frankland and Armstrong's process* (Chem. Soc. Trans. 6, 77). This method, which is unquestionably the most rational and exact, has been adopted to a comparatively limited extent by water analysts in consequence of the special apparatus and manipulative skill which it entails. The method will be described only in outline here, and for full particulars the reader is referred to Sutton's *Volumetric Analysis*, whilst for a critical survey of the methods employed in the organic analysis of water he should not fail to consult Mallet, *Report of the United States National Board of Health*, 1882.

The process is divisible into three parts: (1) the evaporation of the water, (2) the preparation and combustion of the residue thus obtained, and (3) the measurement of the gases evolved in the combustion.

For the *evaporation*, from 100 c.c. (in the case of sewage and highly polluted waters) to

1000 c.c. (in the case of very pure waters) are measured into a clean flask, 20 c.c. of a saturated solution of sulphurous acid being added together with a drop of a solution of ferric chloride; the liquid is then boiled rapidly for a few seconds. This treatment secures the decomposition of carbonates, nitrates, and nitrites, whilst any ammonia is fixed by the sulphurous acid, and this ammoniacal nitrogen, which has previously been determined, must be deducted from the total amount of nitrogen obtained in the combustion. The water is now rapidly cooled, and the evaporation commenced in an apparatus specially designed for the purpose. This consists of a nearly hemispherical glass dish about 4 ins. in diameter and without a lip. It is floated in a shallow copper basin heated below by a water-bath provided with constant feed, and on the flange of this copper basin there rests a truncated conical ring, constructed of lead or copper, and about 3 ins. in height, whilst upon a flange at the top of this again rests a tall glass shade about 12-18 ins. in height. The water for evaporation is placed in a flask which is provided with a delivery tube of special construction ground on to its neck, and which serves, when the flask is turned upside down, to maintain the water at a constant level in the glass dish in which the evaporation is proceeding, for this delivery tube is made to pass through a notch in the truncated conical metal ring, just beneath the glass shade which the latter supports, and delivers into the centre of the glass dish within. In the writer's laboratory, the evaporation of 500 c.c. of water is found to take from 10-12 hours. The evaporation should be continued until the residue is quite dry, and if the water contains only a small amount of total solids it is advisable to add a little ignited calcium phosphate to the dish before commencing the evaporation. In the analysis of sewage, or waters containing much ammonia and no nitrates or nitrites, it is advantageous to use 10 c.c. of a solution of metaphosphoric acid (1:10) instead of the sulphurous acid, as ammonium phosphate loses much less ammonia during evaporation than ammonium sulphite. A little ignited calcium phosphate should also be added to dry the residue in this case. But if there are no nitrates and nitrites and much ammonia, the more satisfactory, although more laborious, plan is to use a little ignited borax instead of the sulphurous or metaphosphoric acid. In this way the ammonia is completely dissipated on evaporation, and as no correction has, therefore, to be applied to the organic nitrogen found, the result is more correct. But as boric acid does not entirely decompose carbonates the accuracy of the organic carbon found by this method may be seriously affected, and it is advisable to make a separate determination of the carbon in a second experiment in which the sulphurous acid method is employed. Unless this method be adopted the results for organic nitrogen in the presence of much ammonia are nearly sure to be highly inaccurate.

If the water contains more than 0.5 part per 100,000 of nitrogen as nitrates and nitrites, the 20 c.c. of sulphurous acid employed above may not improbably prove insufficient for their complete destruction, and in the case of such waters the residue in the dish should be further treated

with 10 c.c. of sulphurous acid, this evaporated off, and if the amount of nitric or nitrous nitrogen exceed 1 part per 100,000 this treatment of the residue with further quantities of sulphurous acid may be repeated twice or three times to secure complete destruction of the nitrates and nitrites.

The *preparation and combustion of the residue* thus obtained is effected by thoroughly mixing with the latter in the dish a small quantity of finely divided and carefully ignited copper oxide. This is then completely transferred to a narrow piece of combustion tubing about 18 ins. long and sealed at one extremity. The dish is again rinsed with a little fine oxide, and this also transferred to the tube. Coarse and carefully ignited oxide of copper (preferably from wire) is then introduced to a depth of about 10 ins., whilst the fine oxide previously introduced will occupy about 2 ins. Upon the stratum of coarse oxide follows a copper gauze cylinder 3 ins. in length, and then another layer of coarse oxide about 1 in. long. The open extremity of the tube is now drawn out over the blowpipe, so that it can be connected with a Sprengel mercury pump. The tube is completely exhausted, and the combustion performed *in vacuo* in the ordinary way, the evolved gases being then drawn over by the pump and collected in a test tube filled with mercury and placed over the lower open extremity of the fall tube in the trough below.

The *volumetric measurement of the gases* (consisting of carbon dioxide, nitrogen, and possibly also nitric oxide and sulphur dioxide) collected as above is carried out in the Frankland gas apparatus, which admits of the measurement of very minute quantities of gas. Three measurements are only necessary. In the first place the gas is treated with a few drops of a saturated solution of potassium dichromate to absorb any sulphur dioxide that may be present. The volume of the gas is then accurately measured, after which it is treated with a few drops of strong caustic potash, which rapidly removes the carbon dioxide, after which the volume of the remaining gas is again carefully ascertained. The residual gas now consists of nitrogen, with possibly a little nitric oxide. It is mixed with a bubble of pure oxygen in order to convert any nitric oxide into nitrous and nitric acids, which are immediately absorbed by the caustic potash present, and then, on adding a drop or two of solution of pyrogallous acid, the excess of oxygen is absorbed and the remaining gas, which consists of nitrogen, is carefully measured. The diminution in volume effected by the caustic potash in the first instance obviously represents the carbon dioxide, whilst the final volume of residual gas, together with one-half of the contraction resulting from the addition of oxygen and pyrogallous acid, represent the total volume of nitrogen. From these volumes the weights of carbon and nitrogen respectively can be calculated. As already pointed out, if sulphurous or metaphosphoric acid has been used in the evaporation, and ammonia is present in the water, the ammoniacal nitrogen (subject to an empirical correction for loss of ammonia during evaporation) has to be subtracted from the total nitrogen found by combustion. A small correction (ascer-

tained by blank experiments made from time to time with the reagents employed in the evaporation and combustion) has also to be applied to the carbon and nitrogen thus determined.

For *Dupré and Hake's method*, see Chem. Soc. Trans. 1879, 159.

In *Dittmar and Robinson's method* of determining organic carbon, the gases proceeding from the combustion tube are first passed through a U-tube containing a solution of chromic acid in 60 p.c. sulphuric acid to absorb moisture and sulphurous acid (the water is evaporated with sulphurous acid for the preparation of the residue), the carbon dioxide being absorbed in a weighed soda-lime tube (Chem. News, 1877, 36, 26). A method of determining organic nitrogen has also been devised by Dittmar and Robinson, and is described below.

(4) *Methods for determination of organic nitrogen only*.—Of these the most common one in use is the well-known

(a) '*Albuminoid ammonia*' process of Wanklyn, Chapman, and Smith (Chem. Soc. Trans. 1867, 591), which does not yield the whole, but only very variable proportions, of the organic nitrogen in different nitrogenous organic substances, although in the case of some—such as leucine, aspartic acid, tyrosine, &c.—which frequently appear as decomposition products of albuminous matters, nearly the whole of the nitrogen is obtained as ammonia (Preusse and Tiemann, Ber. 12, 1906; Mallet, U.S. National Board of Health Report, 1882).

The method has already been described on p. 396.

(b) *Dittmar and Robinson's process*.—In this process the residue, obtained in the same way as for the combustion process, is heated with fused caustic soda, or soda and baryta, in a copper or silver boat placed in a combustion tube in a current of hydrogen, the evolved ammonia being absorbed by very dilute hydrochloric acid, which is subsequently 'Nesslerised' (Chem. News, 1877, 36, 26). The results are accurate, and coincide with those obtained by the combustion process of Frankland and Armstrong.

(c) *Kjeldahl's process*.—This well-known and now much-employed method for determining organic nitrogen was adapted for use in water analysis by Drown and Martin (Chem. News, 59, 272). It appears to give accurate results uninfluenced by the presence of nitrates and nitrites in such quantities as are found in ordinary waters, 500 c.c. of the water are placed in a round-bottomed flask of about 900 c.c. capacity; the volume is then reduced to about 200 c.c. by boiling, and to this, after cooling, 10 c.c. of pure concentrated sulphuric acid are added. The mixture is then cautiously boiled, with the flask in an inclined position, until all the water has been driven off and the acid remains of a white or very pale-yellow colour. After removing the source of heat, add a little powdered permanganate until, on shaking, the liquid becomes green, showing that excess has been added. If a purple instead of a green colour appears, it shows that the whole of the water has not been driven off. When cool, 200 c.c. of water free from ammonia are added, care being taken to rinse round the neck of the flask, and thus wash in any acid which may be adhering there.

WATER.

100 c.c. of sodium hydroxide solution are then added, and the mixture distilled with a Liebig's condenser. (The sodium hydroxide solution is prepared by dissolving 200 grms. of good caustic soda in 1250 c.c. of distilled water, adding 2 grms. potassium permanganate, and boiling down until the volume is rather less than 1000 c.c. making up to 1000 c.c. when cold.) The distillate is collected in a flask containing 50 c.c. of water free from ammonia, and 1 c.c. of dilute pure hydrochloric acid, and during the distillation of the first 50 c.c. the delivery tube of the condenser is made to dip into this acid liquid, whilst during the remainder of the distillation the flask is lowered so that the delivery tube is just above the liquid. The distillation is carried on until the whole of the ammonia has passed over, and the contents of the receiver are then 'Nesslerised' in the ordinary way. The most scrupulous care must be exercised to prevent access of ammonia from the air and reagents; a blank experiment should also be made for control.

Determination of dissolved oxygen.—Much importance is, with very little reason, attributed by some analysts to this determination; it can, moreover, be rarely applied, as the samples must be collected with special precautions if the results are to have any value at all. The various processes in use have been examined by Kisch (Chem. Soc. Abstr. 1892, 98). *Reichardt's* method (Zeitsch. anal. Chem. 1872, 11, 271), as modified by Preusse and Tiemann (Ber. 1879, 12, 1768; Tiemann-Gärtner's Untersuch. d. Wassers, 278), consists in boiling a measured volume of water, and collecting the gases over a hot solution of caustic potash, the oxygen being then estimated either by explosion with hydrogen, or by absorption with potassium pyrogallate. In *Mohr's* method (*Mohr's* Titrimethoden) the sample is mixed with an acid solution of ferrous sulphate of known strength, then with caustic soda to throw down ferrous hydroxide, and after remaining for a few hours (air, of course, fully excluded), the precipitate is re-

in sulphuric acid, and the remaining ferrous sulphate titrated with permanganate. In the *Schützenberger-Risler* process (Bull. Soc. chim. 1873, [ii.] 19, 152; 20, 145; Tiemann-Gärtner's Untersuch. d. Wassers, 277, 288; Catherine Williams and Ramsay, Chem. Soc. Trans. 1886, 760; Bernthsen, Ber. 13, 2277; Roscoe and Lunt, Chem. Soc. Trans. 1889, 552; Dupré, Analyst, 1885, 10, 156) the water is allowed to act on a solution of sodium hydrindigotin disulphonate, which oxygen converts into the blue compound; a standard solution of sodium hydrosulphite is then run in until the liquid again becomes colourless. In *Winkler's* process (Ber. 21, 2843) the water is mixed with a solution of manganous chloride, and then with potassium iodide and caustic potash; the precipitated manganous hydroxide absorbs the oxygen, passing into a higher state of oxidation. On adding hydrochloric acid the higher oxide of manganese gives rise to the liberation of an equivalent quantity of iodine, the amount of which is determined by titration with sodium thiosulphate. According to Kisch (*l.c.*), the results by the *Reichardt-Preusse-Tiemann* method are decidedly lower than those obtained by the *Winkler* process, which is in harmony

with the experience of the writer. The results by *Mohr's* and *Schützenberger's* methods accord very well with those of *Winkler*; but *Winkler's* appears, on the whole, to be the most trustworthy, and the easiest to carry out. A modification of *Winkler's* method has been made by *Rideal* and *Stewart* (Analyst, 1901, 26, 141), and a more recent one reducing it to a colorimetric process by *Rideal* and *Burgess* (*ibid.* 1909, 34, 193).

A full description and discussion of the several methods will be found in *Sutton's Volumetric Analysis*.

The determination of dissolved oxygen has, in recent years, been much practised in connection with the rate at which dissolved oxygen is absorbed by sewage and effluents from sewage works. This matter is of importance as affording a measure of the readiness with which such liquids will remove the dissolved oxygen from a stream into which they are discharged. For *Scudder's* method, see *Fowler's Sewage Works Analyses*, or *Sutton's Volumetric Analysis*.

Determination of carbon dioxide.—(1) The total carbonic acid is determined by completely precipitating as calcium carbonate with an excess of calcium hydroxide (a sufficient quantity of calcium chloride being added to decompose alkaline carbonates), then filtering off the precipitate, and determining the carbon dioxide in it in the usual way (Fresenius, Quant. An.; Tiemann-Gärtner, Die Untersuch. d. Wassers, 213). If the water is saturated with carbon dioxide under pressure, the above method must be preceded by *Rochleder's* process for estimating the gas which escapes on reducing the pressure to that of the atmosphere.

(2) The free and semi-combined carbon dioxide is determined by *Pettenkofer's* method, in which the water is treated with an excess of standard calcium hydroxide solution, and, after the precipitate has separated in a crystalline form, the clear liquid is decanted off, and the excess of lime ascertained in an aliquot part by titration with standard dilute oxalic acid, using phenolphthalein as indicator. If the water contains alkaline carbonates, sufficient neutral calcium chloride solution must be added to decompose them, whilst if there is a considerable proportion of magnesia salts, some ammonium chloride must also be added.

If the carbonic acid thus determined is subtracted from the total obtained according to (1), then the difference represents the combined carbonic acid. To this combined carbonic acid here corresponds, of course, an equal quantity of semi-combined, so that only an excess over and above this can be regarded as free carbonic acid. It must, however, be pointed out that the determination of total carbonic acid generally yields results which are below the truth by 1-1.5 units in 100,000 parts, in consequence of the solubility of normal calcium carbonate itself (v. Walker and Kay, J. Soc. Chem. Ind. 1912, 31, 1013).

Determination of sulphuretted hydrogen.—Colorimetrically with a solution of sodium nitroprusside, using for comparison a standard solution of sulphuretted hydrogen. The latter is standardised by taking a measured volume and adding an excess of decinormal sodium arsenite; shake well, and then acidify with hydrochloric acid. After the arsenious sulphide has com-

pletely subsided, dilute to 300 c.c., and filter through dry paper. Take 100 c.c. of the filtrate, remove acidity by means of solid sodium carbonate, add a drop of starch solution, and then run in decinormal iodine until a blue colour is obtained. This method may, of course, also be employed for the determination of the sulphuretted hydrogen in the water itself if present in sufficient quantity.

In using the colorimetric method, 300 c.c. of the water are treated with 5 c.c. sodium carbonate and 3 c.c. sodium hydroxide; allow the precipitate to subside for 1-2 hours, then decant or filter. To 250 c.c. of the filtrate in a colourless cylinder add 1 c.c. of sodium nitroprusside solution (4 grms. per litre), and for comparison take 245 c.c. distilled water, to which add 2 c.c. sodium hydroxide and as much of the standard solution of sulphuretted hydrogen as is required to produce precisely the same tint as is obtained with the water above. In this manner 0.1 part H_2S per 100,000 can be determined (Tiemann-Gärtner, *Untersuch. d. Wassers*, 232).

Sulphuretted hydrogen may also be accurately determined by means of centinormal iodine solution. 10 c.c. or other suitable volume of the latter are placed in a 500 c.c. flask, and the water added until the colour completely disappears; 5 c.c. of starch solution are then added, and centinormal iodine is run in until a blue colour is obtained, pure distilled water being added up to the 500 c.c. mark from a burette. On subtracting the sum of the volumes of iodine, starch solution, and distilled water added from 500 c.c., the volume of water which reacted with the iodine solution employed is ascertained. A correction should be made for the volume of iodine solution required to produce a blue colour.

BAACTERIOLOGY OF WATER.

The great progress during the past half century made in our knowledge of infectious diseases and of the processes dependent on bacterial life, has necessitated that the subject of water supply should be considered from a bacteriological, as well as a chemical, point of view.

It had even previously been recognised that in making determinations of organic matter, ammonia, nitrates, &c., with a view to ascertaining the fitness or otherwise of water for drinking purposes, the concomitants of the living poisons of zymotic disease and not the morbid matters themselves, which were still more or less hypothetical entities, were being tested for, and that the living poisons themselves must be explored by biological, and not by purely chemical, methods.

Liquid and solid media.

The classical investigations on bacteria by Pasteur, Tyndall, Lister, Nägeli, Cohn, Fitz, Schloessing, Muntz, and others prior to 1880 were practically all made with liquid culture media only. Such culture media labour under several serious disadvantages:—

(1) Facility with which they become contaminated with bacteria and other organisms from the air and other surroundings;

(2) The competition which arises between

the different microbes present may lead to the entire suppression of some through the overwhelming multiplication of others;

(3) The great difficulty of obtaining pure cultivations of specific micro-organisms.

The introduction of solid culture media by Koch at the beginning of the 'eighties, in the last century, led to great developments in bacteriology. An immense variety of investigations were now rendered possible which had long been awaiting attack. These new methods of bacteriological study were at once applied to the identification of the specific micro-organisms of numerous diseases, and to the investigation of the bacteria present, in *air, water, soil*, and all our other surroundings.

By means of *gelatin-plate-culture* it became possible to ascertain the number and the nature of most bacteria present in any material. Thus in the case of water the number and nature of the bacteria present in any sample could be determined, and by this means it was possible to ascertain the effect of any treatment or process of purification on the bacteria present in water. Thus it was applied by the writer in 1885 to the study of the removal of bacteria from water by artificial and natural *filtration*, by *subsidence*, and by *precipitation*.

The results obtained in investigations of this kind led to a great modification of the opinions which had previously been entertained with regard to the value of these processes in removing the zymotic dangers of water. Thus it was found that bacteria could be almost wholly removed from water by the process of sand filtration which had a comparatively insignificant effect on the organic matter and other ingredients discoverable by chemical analysis.

Similarly these methods of bacteriological investigation enabled such processes of water purification to be readily controlled. Thus if the safety of a water-supply depends on the efficiency with which the removal of bacteria by filtration is carried out, it is obvious that this efficiency should be continually controlled by bacteriological examination, so that any defect in the working of the filters may at once be detected and rectified. The systematic control of water-works by bacteriological examination is now being very widely carried on with great benefit to the communities concerned.

With the discovery of the specific bacteria of cholera, of typhoid fever, and of many other diseases, attempts were naturally made to find these specific pathogenic bacteria in contaminated water-supplies. The chance of such discovery by the ordinary method of plate-cultivation is, of course, hopelessly remote, because a single pathogenic organism must almost inevitably be accompanied in water by a host of non-pathogenic individuals, and amongst these multitudes of harmless forms the few harmful ones will under ordinary circumstances be overlooked, whilst, in the small quantities of water operated on, the pathogenic forms may be absent, although present in a larger bulk.

To surmount these difficulties, the natural device was to provide conditions which would be favourable to the particular pathogenic form being sought for and less favourable or even antagonistic to the multitude of non-pathogenic forms with which it would be accompanied.

We may call the provision of such conditions the method of *enrichment or preferential culture*.

Such a method of enrichment was very satisfactorily applied by Koch to the discovery of the *cholera-bacillus* in the water of the Elbe at Hamburg during the epidemic of 1892. If 90 c.c. of the water under examination be incubated for 18 hours at 37° with 10 c.c. of a solution containing peptone 10 p.c., and sodium chloride 10 p.c., cholera bacilli will be found in the thin surface pellicle, and from this cultures are made.

Typhoid fever is, of water-borne diseases, the most important in Western Europe. An enormous amount of labour and ingenuity have been devoted in recent years to the discovery of the bacillus of this disease in water. That the problem is a very difficult one may be gathered from the fact that until recently its detection even in the discharges of typhoid patients was very frequently abortive.

The special difficulty attending the discovery of the typhoid bacillus depends on the circumstance that even in the intestine of the typhoid patient it is enormously outnumbered by other bacteria, and especially by the *Bacillus coli communis*, which, discovered by Escherich in 1886, has in recent years achieved the very greatest celebrity in the bacterial world.

Practically all conditions which are favourable to the typhoid bacillus are equally or even still more favourable to the *B. coli*, and for a long time all methods of favouring the typhoid bacillus at the expense of the *B. coli* proved futile. Much interest was, therefore, excited when in 1903 Roth announced that the *B. coli* was more disadvantageously affected than the typhoid bacillus by solutions of caffeine.

Experiments made by Kloumann¹ in 1904, however, showed that the differential effect on the two bacilli was only very slightly in favour of the typhoid bacillus.

A method of testing for typhoid bacilli in water and other liquids was elaborated by Hoffmann and Ficker in 1904; it was also based on the inhibitory action of caffeine and of crystal-violet on the *B. coli*. The method will be best understood by the following description of the manner in which it was successfully employed by Jaksch and Rau (1904) to detect typhoid bacilli in the drinking water supplied to Prague:—

900 c.c. water from a service tap were added to the Hoffmann and Ficker culture-medium, consisting of 10 grms. nutrose, 5 grms. caffeine, and 0.01 gm. crystal-violet, in 100 c.c. water.

The mixture was then incubated at 37° for 13 hours, when it was to be presumed that any typhoid bacilli originally present would have extensively multiplied. Loopfuls of this large cultivation were then withdrawn and spread on the surface of Drigalski and Conradi Plates (agar, meat extract, peptone, nutrose, lactose, sodium chloride, crystal violet and litmus), which were then incubated at 37° for 24 hours. On these plates the *B. coli* colonies are red (acid litmus) and non-transparent, whilst those of the typhoid bacillus are blue with a violet-tinge, transparent, resembling dewdrops, and smaller than the *B. coli* colonies. In the Prague experiments these plates gave only a few red

blue and transparent.

The latter were sub-cultured, and, according to Jaksch and Rau, gave results in the most varied tests (including agglutination, toxicity, and immunisation) which were identical with those obtained with the true typhoid bacillus.

Other solid media which have proved of great value in distinguishing between coli-like and typhoid-like colonies are Loeffler's malachite-green agar, and McConkey's bile-salt-neutral-red agar, both of which will be referred to later.

By far the most extensive, interesting, and systematic search which has ever been made for the typhoid bacillus in natural waters is that carried out by Houston on the waters of the three rivers—Thames, Lea, and New River—from which the greater part of the London water supply is obtained. As this investigation illustrates the most approved methods which are now available to the bacteriologist, it will be considered here in some detail.

Two hundred and ninety-four experiments in 8 series were made with 156 samples of raw river water (52 Thames, 52 Lea, and 52 New River) during the 12 months ended July 31, 1908. The total volume of water dealt with was $294 \times 100 = 29,400$ c.c. The total number of bacteria in this volume of water (as ascertained by gelatin-plate cultivation for 3 days at 20°–22°) was 135,687,500. The total number of colourless (or nearly colourless) colonies sub-cultured from the Drigalski or similar plates was 7329. These 7329 selected colonies form but a small fraction of the millions of bacteria which were excluded owing to the temperature of incubation, the composition of the media employed, and the fact of their appearing on the plate-cultures as coloured colonies.

The following tabular summary indicates the method adopted in this exhaustive investigation:—

Direct Plating on Solid Media.

Series I. 100 c.c. of the sample of water were centrifuged and the resulting deposit spread over a number of plates consisting of malachite-green (1 in 5000), saccharose, dulcitol, salicin, neutral-red, bile-salt, peptone, lactose, agar. The plates were incubated at 40°–42° for 24 hours, and the colourless colonies sub-cultured into special media, as described in the next table.

Series II. Same as Series I, but the proportion of malachite-green was 1 in 10,000.

Series III. Same as Series I, but the medium used in the plates contained no malachite-green.

Series IV. Same as Series I, but the proportion of malachite-green was 1 in 20,000, 1 in 40,000, and 1 in 80,000.

Primary Liquid Cultures followed by Plating on Solid Media.

Series A. 100 c.c. of the sample of water were added to bile-salt-glucose-peptone medium containing malachite-green in proportion of 1 in 1000, 1 in 2000, 1 in 4000. This liquid was incubated at 40°–42° for 24 hours, and then plated on the same medium as was employed in Series I, 10 colourless colonies were in each case sub-cultured and tested as described.

Series B. Same as Series A, but malachite-green in the liquid medium was in proportion

¹ Kloumann, *Centralbl. f. Bakteriologie*, 1904, 36, 312.

of 1 in 8000, 1 in 16,000, 1 in 32,000. Subsequently plated on same medium as that used in Series II.

Series C. Same as Series A, but the liquid culture medium consisted of meat-broth only without malachite-green or any other additions. Subsequently plated on same medium as that used in Series I.

Series D. Same as Series C, but instead of cultivating 100 c.c. of water in one

portion, 10 cultures of 10 c.c. each were made.

The following table shows the behaviour of 32 strains of the typhoid bacillus, on the one hand, and of the 7329 suspicious colonies isolated from the raw waters, on the other. *It will be seen that not one out of all these 7329 different microbes, although suspicious in certain features, gave reactions agreeing in their entirety with those of the typhoid bacillus.*

VERIFICATION TESTS FOR TYPHOID BACILLUS.

	Test 1	Test 2	Test 3	Test 4	Test 5	Test 6
Description of microbe.	Proskauer's and Capaldi's No. 2 medium ¹ (with inner tube).	Lactose-saccharose dulcitate-salicin-medium (with inner tube).	Proskauer's and Capaldi's No. 1 medium ² modified (with inner tube).	Glucose-neutral red broth cultures (with inner tube).	Peptone-water medium.	Gelatin sugar media:—galactose, glucose, levulose, maltose, and mannite respectively.
RESULTS CHARACTERISTIC OF TYPHOID BACILLUS.						
32 strains of typhoid bacillus from a number of different laboratories.	Acid, no gas	No visible change (No acid, no gas.)	No visible change. (No acid, no gas.)	Purplish tint. (No gas, no fluorescence.)	No indole	Acid, but no gas with all five sugars. No liquefaction.
RESULTS WHICH EXCLUDE, AS NOT TYPHOID BACILLUS, THE SUSPECTED MICROBES.						
7329 colourless (or nearly colourless) colonies, sub-cultured.	No acid, or acid and gas	Acid or gas-formation.	Acid or gas-formation, or decided growth.	Gas or fluorescence. (Absence of purplish tint.)	Indole	Gas formation in one or all of the sugar media. (Liquefaction.)

¹ Solution of peptone and mannite.

² Solution of asparagine, mannite, glucose, galactose, levulose, maltose, magnesium sulphate, sodium chloride, calcium chloride, potassium hydrogen phosphate, and litmus.

From the very nature of this investigation—the search for a specific microbe in a natural water which at some period in its history is practically certain to have received this microbe in comparatively small numbers—it is impossible to make it really exhaustive. Houston has, however, amplified his previous investigation in a very suggestive manner. Realising that the objection might be raised that the method adopted may not be capable of detecting a very small number of typhoid bacilli in the presence of a very large number of other microbes, he devised a mode of procedure which enabled him to affirm that in each particular sample of water examined there were *not more* than a certain definite number of typhoid bacilli in a given volume. The method adopted was this:—

Each sample of raw river water was divided into two equal portions of 500 c.c. (A and B). The A sample was inoculated with a very small number of typhoid bacilli. The B sample was not so infected, and was, therefore, normal raw river water. The subsequent procedure was exactly the same in each case, both samples A and B being treated exactly alike. The 500 c.c. of water were centrifuged and the resulting deposit spread over 16 plates prepared with solid medium of the following composition:

Agar, 2 grms.; peptone, 2 grms.; bile-salt, 0.5 grm.; lactose, saccharose, adenite, raffinose,

and salicin, each 0.2 grm., made up with water to 100 c.c. and tinted with 0.4 c.c. of a 1 p.c. solution of neutral red. In some of the experiments malachite-green was added to the above, in the proportion of either 1 to 10,000, or 1 to 5000 of the medium.

Of the 24 experiments, 14 were carried out with raw Lea, and 10 with raw Thames, water. These waters contained on an average 62,688 bacteria per 1 c.c. (gelatin at 20°–22°, 3 days' incubation). The worst sample contained 760,000 and the best sample 1200 bacteria per 1 c.c. Thus in the 12 litres (500 c.c. × 24) of raw water (B samples) examined for typhoid bacilli there were 752,256,000 bacteria present.

The total number of colonies selected for study was 5451 from the infected A samples, and the same number (5451) from the non-infected B samples. The average number of typhoid bacilli artificially added to the A samples was 2.242 per 1 c.c. or 1121 per 500 c.c. The average number of typhoid bacilli isolated from the A samples was 14.54 per 500 c.c. of sample. It may be argued fairly, therefore, that if only $\frac{1}{14.54}$ of the above number of typhoid bacilli had been present in the infected sample this microbe would still have been detected by the method of investigation adopted; but $\frac{1}{14.54} \times$

2-242=0.154 typhoid bacillus per 1 c.c., or 1 typhoid bacillus in 6.5 c.c. would have been detected.

From the uninfected B samples, out of the 5451 colonies selected for special study, one, and only one, consisted of bacteria which resembled the typhoid bacillus very closely.

It will be instructive to record the observations which were made on submitting this typhoid-like microbe (Lea W. 694 ? *B. typhosus*, Houston) to the several tests used in the diagnosis of typhoid bacilli.

*Characterisation of typhoid-like bacillus from raw river water (Lea W. 694 ? *B. typhosus*, Houston).*

Morphology.—A motile multiflagellate bacillus. The rods seemed shorter than in most strains of *B. typhosus*.

Gelatin and agar slope-cultures.—Possibly the growth was slightly less filmy in character than that of the true *B. typhosus*.

Glucose-bile-salt agar-slope (neutral red).—The streak somewhat brighter and cleaner red than in most strains of *B. typhosus*.

Lactose-bile-salt agar-slope (neutral red).—Colourless streak.

Potato.—No visible growth (5 days at 37°).

Nitrate-broth.—Reduces nitrates to nitrites.

Peptone-water at 55°F.—No visible growth after 5 days; on transferring tube to incubator at 37°C. growth occurred within 24 hours.

Indole test.—No indole formation (5 days at 37°).

Liquid peptone (1 p.c.) media containing separately 1 p.c. of the substances stated and tinted with litmus. Sorbite and inosite are only used in 0.2 p.c. solution. Acid but no gas in sorbite, mannite, glucose, levulose, galactose, and maltose respectively (2 days at 37°). No change in inulin, inosite, saccharose, salicin, adonite, lactose, dulcete, and raffinose respectively (5 days at 37°).

Gelatin glucose medium tinted with litmus.—Acid but no gas formation.

Voges and Proskauer's reaction.—Negative result, 5 days.

Gelatin.—No liquefaction after one month at 20°.

Litmus milk.—Slight acid but no coagulation (5 days at 37°).

Glucose-neutral-red-broth cultures.—No gas, no fluorescence characteristic purplish tint.

Lactose-saccharose-dulcete-salicin-peptone medium tinted with litmus.—No change (2 days at 37°).

Proskauer and Capaldi's Medium No. 1 (modified).—No change (2 days at 37°).

Proskauer and Capaldi's Medium No. 2.—Acid but no gas.

Agglutination experiments and tests for pathogenicity.

Anti-typhoid serum.—Microscopically, 1 : 200 almost instantaneous clumping, 1 : 800 very fair clumping, 1 : 2000 little or none. *B. typhosus* tested with the same serum gave very similar results but appeared to be clumped slightly more rapidly and in slightly higher dilutions. The difference, however, if any, was not well marked.

* *Serum of an animal immunised with the suspected microbe (Lea W. 694 ? *B. typhosus*, Houston).*—Microscopically, 1 : 200 very rapid and satisfactory clumping; 1 : 2000 good, but not quite complete clumping within half an hour.

B. typhosus tested with the same serum gave very similar results, but was perhaps clumped a little more slowly and in slightly lower dilutions. The difference, however, if any, was not well marked. Microscopically, the titre limit was about 1 : 8000 (18 hours) and was practically the same for both microbes.

Pathogenicity.—2 c.c. of a broth-culture injected subcutaneously into a guinea-pig produced a swelling and illness with recovery. A guinea-pig intraperitoneally inoculated with 5 c.c. of a broth-culture died in less than 24 hours.

On the results of this laborious investigation, which had extended over more than two years and which had been conducted with the most meticulous care and regardless of time or money, Dr. Houston very cautiously remarks: 'If this microbe had been isolated from a case of typhoid fever (or from a suspected case) I do not think any serious hesitation would have been felt in describing it as *B. typhosus*.'

It would be impossible to produce more eloquent testimony than the above as to the enormous and almost prohibitive trouble which a systematic and conscientious search for the typhoid bacillus in natural water entails.

Comparative unimportance of searching for the typhoid bacillus in water.—The almost hopeless nature of the search for the typhoid bacillus in natural waters is of the less importance as the anxiety to detect this microbe in water is, for the most part, based upon an entire misconception of the objects of water examination. The object of a water examination is, in general, not to determine whether the particular sample of water contains typhoid bacilli and is, therefore, capable of carrying typhoid to the consumer, but to discover whether the water is likely at any time to contain such infective material.

Now any water which receives sewage matters must be regarded as a possible carrier of typhoid infection, for at any time these sewage matters may be derived from persons suffering from typhoid. Thus any sewage-contaminated water is a potential carrier of typhoid unless it has been subjected to conditions which would ensure the removal of the possibly present typhoid bacillus. Thus the all-important thing is to ascertain whether a given water has been contaminated with sewage, in what proportion such contamination has taken place, and whether the water since such contamination has been submitted to conditions which would remove or destroy typhoid bacilli should they have gained access with the sewage matters.

Firstly, as regards the detection of sewage contamination. Excremental contamination, if sufficient in amount, can be revealed with more or less certainty by chemical analysis, which can indeed even distinguish between whether such pollution is recent or remote in point of time, but in order to ascertain the fate of bacteria gaining access to water recourse must be had to biological methods. If there were bacteria absolutely characteristic of sewage, the determination of their presence would be sufficient to

prove the danger of a water. Unfortunately we do not know of any bacteria which satisfy the condition of being *absolutely* characteristic of sewage, so we must be satisfied with a second best qualification for diagnostic purposes by those which are *very* characteristic of sewage.

The microbe which is most characteristic of the intestinal discharges of man and the higher animals is, as its name implies, the *B. coli communis*, and a great amount of time and ingenuity has been devoted to its accurate and expeditious discovery in water and other materials.

In identifying a particular organism, whether plant or animal, we depend on recognising in the individual a certain group of specific characters which are more or less arbitrary. The botanist at first tried to classify and distinguish bacteria by external appearances alone; he measured the length and breadth of these minute organisms; he counted the number of flagella with which some of them are provided; he was very careful to observe whether they were square or round at the ends, and so forth.

These morphological characters have, however, long been recognised as inadequate for purposes of identification, since organisms exhibiting the closest morphological similarity have been found to differ enormously in other respects.

After the introduction of Koch's methods much attention was directed to the macroscopic appearances to which the organisms give rise when grown on a variety of solid media, by which means microscopically similar bacteria can often be differentiated.

Some 35 years ago the writer commenced distinguishing bacteria, which were similar in form and in cultural appearances, by differences in the chemical changes which they could bring about in certain media. Thus he found that the capacity to reduce nitrates to nitrites was in some cases a valuable means of distinguishing between otherwise similar bacteria. This reduction of nitrates has been extensively used for diagnostic purposes, more especially by American bacteriologists. Somewhat later he devoted much attention to the fermentation of carbohydrates, polyhydric alcohols, and hydroxy-acids, by means of pure cultivations of micro-organisms, and showed how capricious is the power possessed by different bacteria in this respect. Thus perhaps one microbe will ferment glucose, mannite, and glycerol, but not dulcitol or glyceric acid, another will ferment glucose, mannite, and dulcitol, &c.

There are, however, many bacteria which more or less simulate the characters of the typhoid bacillus on the one hand, and of the *B. coli* on the other; such forms exhibit almost every degree of approximation to one or other of these two types, from which they can only be distinguished by applying a number of tests. Such forms are designated as *atypical*, and what their relationship to the typical typhoid and coli bacteria may be is a matter of uncertainty. Possibly in some cases they may have been typical forms originally, but under the particular conditions to which they have been submitted they have lost some of their characters. Thus it is often found that the *B. coli*, on prolonged

artificial culture, may lose either or both its indole-producing and milk-curdling properties.

This mode of differentiating between otherwise very similar forms of bacteria has been greatly extended within recent years. In the following table the classification of the Typhoid-coli group of bacteria into seven sub-groups has been attempted:—

TYPHOID-COLI GROUP.

Sub-groups	Glucose	Acid gas	Lactose	Acid gas	Dulcitol	Acid gas	Saccharose	Acid gas
I.								
<i>B. Typhosus</i> :	+	-	-	-	-	-	-	-
<i>B. dysenteriae</i> :	+	-	-	-	-	-	-	-
<i>B. faecalis-aeruginosa</i> :	-	-	-	-	-	-	-	-
II.								
<i>B. enteritidis</i> (Gaertner) :	+	+	-	-	+	+	-	-
<i>B. paratyph</i> :	+	+	-	-	+	+	-	-
<i>B. paracoli</i> :	+	+	-	-	+	+	-	-
III.								
Bacillus from urine :	+	+	-	-	-	-	+	+
IV.								
<i>B. acid lactici</i> (Huppe) :	+	+	+	+	-	-	-	-
V.								
<i>B. coli</i> (Escherich) :	+	+	+	+	+	+	-	-
VI.								
<i>B. pneumoniae</i> (Friedländer) :	+	+	+	+	+	+	+	+
VII.								
<i>B. capsulatus</i> (Pfeiffer) :	+	+	+	+	-	-	+	+
<i>B. lactis aerogenes</i> (Escherich) :	+	+	+	+	-	-	+	+
<i>B. cloacae</i> (Jordan) :	+	+	+	+	-	-	+	+

It is obvious that by increasing the number of biochemical tests many further variations of a given type of organism may be discovered, and, for the purpose of more precisely defining a particular microbe, bacteriologists have introduced biochemical tests involving the use of a variety of organic compounds—more especially carbohydrates, polyhydric alcohols, and glucosides. These tests generally consist in ascertaining whether an organism under investigation gives rise to acid or gas, or both, or neither, in a suitable nutritive medium containing one of these substances. The following list of substances employed in this manner will give some idea of the degree to which these biochemical tests have been complicated in recent years: adonite, asparagine, dextrin, dulcitol, erythrite, galactose, glucose, glycerol, glycol, isodulcitol, lactose, laevulose, maltose, mannite, mannose, nutrose, raffinose, sucrose, salicin, sorbite, and starch. The above list by no means exhausts the number of organic substances which are acted on by bacteria, and by means of which, therefore, differences can be established.

Although such tests are extremely useful for the more precise definition of particular micro-organisms, they must be employed with discrimination, for as the writer long ago pointed out, these fermentations, as well as other characters of bacteria, are liable to be lost through conditions of environment, and he has also shown how in some cases they may

restored by resorting to particular methods of culture and training.

It is obvious that it would be impracticable to resort to such numerous tests in the ordinary bacteriological examination of water in which we are concerned with the detection of sewage or excremental contamination, unless some very great advantage should result from such multiplication of tests, and this is not the case at present.

Quantitative determination of B. coli in water.

—If we regard the *B. coli* provisionally as the best indicator of contamination with the living bacteria of animal refuse, we shall obviously view its presence with the more suspicion the larger the numbers in which it is discovered in a given volume of water.

The numerous methods which have from time to time been devised for detecting *B. coli* will be passed over, and only the one which in this country at any rate has superseded all others will be described.

An important departure in practical bacteriology was the introduction by McConkey and Hill ('Bile-salt broth. A simple test for faecal contamination.' Thompson-Yates Laboratories Report, 1901, 4, [i.] 151) of a medium for the preferential culture of the *B. coli* and allied microbes from mixtures of micro-organisms. The essential ingredients of this medium are sodium taurocholate (bile-salt) 5 grms., glucose 5 grms., peptone 20 grms., water (tinted with litmus) 1000 c.c. Incubated in this liquid at 37°-42° bacteria of the *B. coli* group give acid and gas in 48 hours. Some bacteriologists use lactose instead of glucose, thus restricting the gas production to *B. coli* and its still closer allies. With this liquid medium in Durham fermentation-tubes cultivations of the water are made in the following quantities: 100, 10, 1, 0.1, 0.01, 0.001, 0.0001, 0.00001 c.c. The concentration of the medium should in all cases be approximately the same as that given above. In order, therefore, that the volumes of liquid incubated may not be inconveniently large, the 10 and 100 c.c. of water are introduced into correspondingly stronger McConkey media.

A positive reaction, i.e. the production of acid and gas, in any of these culture-tubes signifies that at least one coli-like microbe must have been introduced with the portion of water added. Thus, if acid and gas had been obtained, in a particular case, with all the tubes from 100 to 0.1 c.c., this would mean the 'presumptive' presence of at least one *B. coli* in 0.1 c.c., and its absence in 0.01 c.c. and smaller volumes of water.¹

¹ There is one element of uncertainty connected with such tests made in liquid media which appears to be tacitly ignored by all bacteriologists who make use of them, and that is that the particular microbe sought for may in the process of cultivation in the liquid medium become hopelessly outnumbered or even suppressed by the much more abundant proliferation of some other microbe or microbes present in the mixture.

Thus the McConkey medium may be taken as especially favourable for the proliferation of bacteria of the *B. coli* type, but the water-bacteriologist is in general restricting his search to those bacteria which are sufficiently like typical *B. coli* as to produce acid and gas in the medium. Is it not possible that the bacteria capable of producing both acid and gas may be so greatly outnumbered by microbes not giving this reaction that the more typical *B. coli* forms may be so much kept in abeyance that no acid and gas reaction is obtained? Under these circumstances he would

• In order to ascertain whether the 'presumptive' *B. coli* is typical or not, the tube containing the smallest portion of water which has given rise to acid and gas in the McConkey medium is plated on a solid medium of the following composition: Agar 20 grms., peptone 20 grms., sodium taurocholate (bile-salt) 5 grms., lactose 10 grms., neutral red (1 p.c. solution) 4 c.c., made up to 1000 c.c. with water. After 12 hours' incubation at 37°, the colonies will be distinctly visible, and those which are most likely to be *B. coli* will have a strong red colour owing to the acid produced by this microbe in the medium. Five of the most typical red colonies are separately inoculated into 5 glucose-litmus broth tubes, which are then incubated at 37°. Any of these 5 tubes which develop acid and gas are then each further inoculated into tubes of the following media which are then incubated at 37°:—

(a) Neutral red broth to be examined for fluorescence.

(b) Litmus lactose-broth to be examined for acid and gas.

(c) Ordinary broth to be examined for indole.

(d) Litmus-milk to be examined for acid and coagulation.

(e) Gelatin to be examined for non-liquefaction.

The above glucose-tubes from which these inoculations have been made are also microscopically examined to see whether the microbe possesses the characteristic form and motility of the *B. coli*.

A microbe fulfilling these conditions has been designated by Houston as 'Flaginac' *B. coli*, from Fl—fluorescence in neutral-red broth, ag=acid and gas in lactose, in=indole in peptone broth, ac=acid and coagulation in litmus-milk.

The typical *B. coli* from human faeces gives these reactions, but, of course, it is possible to further differentiate between coli-bacteria by additional tests, such as fermentation of sucrose, dulcitol, mannitol, &c., but at present there would not appear to be any advantage in such multiplication of tests in the ordinary examination of water.

The following table summarises an interesting investigation made by Houston on the proportion of 'Flaginac' *B. coli* found amongst the coli-like microbes obtained from different sources:—

FLAGINAC *B. COLI*.

Source	Number of specimens of <i>B. coli</i> or coli-like microbes on which flaginac percentage is based	P.c. of microbes which flaginac <i>B. coli</i> .
Milk	343	61
Human faeces	101	85
Sewage	several hundreds	65-85
Oysters	464	43
Estuarial waters	183	66
Water-cress	81	40
Washings of cress	52	52
Water in which was grown	42	76
London filtered water	232	31

obviously draw the conclusion, and quite erroneously, that acid and gas producing microbes (and, therefore, *B. coli* amongst them) were absent. This is a matter which requires much further investigation before the conclusions as to absence of *B. coli* generally drawn can be justified.

In the following table are recorded the results of some very suggestive pioneering experiments made by McConkey (1905), undertaken with the object of ascertaining whether there is any marked difference in the types of *B. coli* found in the excreta of man and some of the common domestic animals respectively. Should it be possible to establish such a difference, an important means of distinguishing between human and animal excrementitious contamination of water would be obtained.

Such an investigation would have to be enormously extended before results capable of being used for diagnostic purposes could be obtained.

An attack on the same important problem was also made by Dr. Wm. G. Savage (1904-5) in an extremely laborious investigation, which he has summarised in the foregoing table.

The absence of streptococci in the faeces of the pig is extremely remarkable.

It is convenient to classify waters tentatively

B. COLI FROM HUMAN AND ANIMAL EXCRETA (McCONKEY).

Group	Fermentation of		Number of lactose-fermenting Coll-form microbes isolated and experimented with			Results in percentages

Sheep No. 2	10 to 100 millions	10 to 100 millions	10 to 100

according to the results of the examination for *B. coli*, thus :—

CLASSIFICATION OF WATER BY B. COLI TEST. (1 c.c. of sewage is assumed to contain 100,000 *B. coli*.)

Class	Volume of water examined	<i>B. coli</i> per 1 c.c.	Pollution in sewage
	c.c.		per cent.
I	— in 100	0	—
II	+ in 100	0.01	0.00001
III	+ in 10	0.1	0.0001
IV	+ in 1	1	0.001
V	+ in 0.1	10	0.01
VI	+ in 0.01	100	0.1
VII	+ in 0.001	1,000	1
VIII	+ in 0.0001	10,000	10
IX	+ in 0.00001	100,000	100 (pure sewage)

This classification must not, however, be interpreted too rigidly, as it is based on the assumption that *B. coli* is always derived from faeces and that this microbe is incapable of multiplication under any circumstances after incorporation in what is known as 'sewage.'

In the two following tables are recorded the results of the ordinary bacteriological examination of a number of typical waters. The tables sufficiently explain themselves.

Storage of water.—In 1886 (Water Purification, its Biological and Chemical Basis, Trans. Inst. Civil Engineers, 1886) the writer pointed out the great importance from a theoretical point of view of storage for the purification of surface waters. In 1892, again, he investigated the influence of storage on the bacteriological purity of the river waters abstracted for the supply of London, and showed that there is a most striking reduction in the number of

suspended micro-organisms during storage in large reservoirs.¹

¹ Appendixes to Minutes of Evidence, Roy. Commission on Metropolitan Water Supply, 1893, 469-475. See also "Micro-organisms in Water," P. Frankland and G. O. Frankland, London, 1894, pp. 99, 126, 181-142, 184.

The great importance of storage from the hygienic point of view was further manifest from the experiments made on the fate of pathogenic bacteria introduced into natural waters, and which showed that the duration of life of these bacteria under such conditions is generally very short.

In 1891-4 the writer had the opportunity of greatly extending his observations on this subject, as he was requested by a Committee of the Royal Society to make, in conjunction with the late Professor Marshall Ward, F.R.S., a special inquiry into the vitality of pathogenic bacteria in potable waters (see Proc. Roy. Soc.). The experiments were restricted to the study of the behaviour of the anthrax bacillus (and its spores), the typhoid bacillus, and the *B. coli communis*, and the potable waters employed were those of the Thames, Loch Katrine, and deep-well water from the chalk, these being fairly typical of the different kinds of water used for drinking purposes in this country. Experiments were made with these waters in their natural, and also in a sterilised, condition.

The results obtained may be summarised as follows:—

(1) Unsterilised water infected with anthrax bacilli containing spores was still virulent after being kept for 7 months.

(2) Anthrax bacilli taken directly from an animal dead of anthrax, and, therefore, free from spores, died rapidly (mostly in 5 days) when introduced into unsterilised water kept at low temperatures (5° and 13° in these experiments), but when introduced into the same waters and kept at 19°, the bacilli formed spores, and the latter were still present in enormous numbers even 42 days later, and doubtless for a much longer period still. This remarkable difference in behaviour is accounted for by the fact, previously discovered by Koch, that anthrax bacilli do not form spores below 16°.

The following results were obtained by introducing typhoid bacilli from one and the same cultivation and in the same numbers into each of the waters at one and the same time:—

Unsterilised water	Life of typhoid bacilli
Thames water (Oct. 19, 1893) 9°-12°	Between 0 and 13 days
Loch Katrine water (Oct. 19, 1893) 9°-12°	
Deep well water (Oct. 10, 1893) 9°-12°	
In two other separate experi- ments with unsterilised Thames water (May 11, 1893)	" 25 " 34 "
and (Jan. 16, 1894) : :	" 20 " 27 "

In all these experiments only 1 c.c. of water was examined for typhoid bacilli, and the method of search, the best known at the time, was that due to Parietti, in which the water is cultivated in a phenol-broth medium at 37°, which on becoming turbid is submitted to plate-cultivation, the colonies obtained being then examined in detail for identification.

It is particularly interesting to compare with the above results those obtained by Houston in a perfectly similar inquiry and making use of all the most modern developments of bacteriological technique. Dr. Houston made 18 experiments on raw Thames, Lea, and New River waters, infecting them with typhoid bacilli (the number added being in all but three experiments very large, see table below). The presence of the bacillus was tested for at weekly intervals in 1 c.c. by means of a medium con-

taining *Agar-bile-salt-dulcitol-lactose-saccharose-salicin-peptone-neutral-red-malachite-green*, and which is specially designed to favour the growth of this microbe whilst repressing that of most others. The results may be summarised in the following statement:—

In 3 experiments the typhoid bacillus was undiscoverable in 1 c.c. in 1 week.

In 10 experiments the typhoid bacillus was undiscoverable in 1 c.c. in 3 weeks.

In 16 experiments the typhoid bacillus was undiscoverable in 1 c.c. in 4 weeks.

In 18 experiments the typhoid bacillus was undiscoverable in 1 c.c. in 5 weeks.

Thus, notwithstanding the great advances made in the technique of testing for the typhoid bacillus, the results obtained by Houston are essentially similar to those obtained by the writer 15 years previously. Houston has, however, extended the investigation in an interesting manner by ascertaining the length of time required before even 100 c.c. of the infected water gave a negative result on being tested by the most modern methods for the presence of the typhoid bacillus. The whole of Houston's investigations (both for 1 c.c. and for 100 c.c. of water tested) is instructively summarised in the table on p. 414.

This table shows, on the one hand, that whilst in each case nearly all the typhoid bacilli are destroyed by a single week's residence in these raw river waters, a few individuals persist for a much longer period of time. This illustrates in a very interesting and instructive manner a principle emphasised by the writer some 16 years before, 'that one of the factors determining the longevity of pathogenic bacteria placed in water, or for the matter of that placed in any unfavourable surroundings, is the absolute number in which they are present. In other words, amongst, for instance, 1000 bacteria taken from a given source there may be *some individuals* which will resist a particular reverse influence, whilst amongst 10 bacteria taken from the same source there may be *none* capable of resisting the adverse influence in question' (P. F. Frankland, Proc. Roy. Soc. 1894, 66, 486).

Before leaving the subject of the behaviour of the typhoid bacillus in water, mention must be made of some extremely interesting and ingenious experiments by the American bacteriologists, Jordan, Russel, and Zeit, in 1903. These investigators endeavoured to imitate natural conditions more closely than has been done in any other experiments by placing the typhoid-infected waters in permeable sacs made of celloidin and parchment, and then by submerging these in river, canal, or lake water, their contents were exposed to the influence of the dialysable substances present in the water under natural conditions.

Zeit experimented with Lake Michigan water and Chicago river water, the natural bacterial content of which varies between 68 and 2000 microbes per 1 c.c. in the case of the Lake, and between 80,000 and 1,500,000 microbes per 1 c.c. in that of the river water. Parallel experiments were made with infected water placed in ordinary bottles and in permeable sacs respectively. The typhoid bacilli introduced varied between 500 and 2,000,000 per 1 c.c. The destruction of the typhoid bacillus

was taken as complete when negative results were obtained on cultivating 5 c.c. of the water, the death of the typhoid bacillus being generally confirmed by the subsequent cultivation, a few days later, of much larger volumes, sometimes as much as 800 c.c. of the water. Nine experiments were made with the Michigan Lake water, the typhoid bacillus being never found after the eighth day. Five experiments were made with the Chicago River water, the typhoid bacillus being never found after the third day.

Jordan experimented with the water of the Chicago Drainage Canal, which usually contains from 100,000 to 400,000 bacteria per 1 c.c. This water was infected with from 180 to 857,000 typhoid bacilli per 1 c.c. In these experiments, however, the maximum volume

submitted to cultivation appears to have been only 1 c.c., and from negative results with even smaller volumes the death of the typhoid bacillus seems to have been concluded. Twenty-eight experiments were made in permeable sacs submerged in the canal, the typhoid bacillus being never detected after the second day, excepting in one experiment in which it was still found on the tenth day.

Russel's experiments were made with the Illinois River water, which contains from 1800 to 4000 bacteria per 1 c.c. This water was infected with 540 to 20,000 typhoid bacilli per 1 c.c. However, in these experiments, again, 1 c.c. appears to have been the maximum volume of water cultivated for the detection of the typhoid bacillus. Fourteen experiments

were made in permeable sacs submerged in the Illinois River, the typhoid bacillus being never found after the third day, excepting in one case in which it was detected on the ninth day.

More recently, again, Houston has taken typhoid bacilli not from cultivations but from the human subject and introduced them into raw Thames water. He found that such bacilli perished very rapidly—much more quickly in fact than had been his experience with cultivated strains of the microbe.

The uncultivated typhoid bacteria were obtained from the urine of a 'typhoid carrier,' and on Aug. 9, 1910, the centrifuged deposit (3.5 c.c.) from 389 c.c. of urine was added to 8000 c.c. of raw Thames water; the number of typhoid bacilli was determined as follows:—

At time of mixture, 770,000 typhoid bacilli per 1 c.c. of river water.

After 1 week, 4 typhoid bacilli per 1 c.c. of river water.

After 2 weeks, 0 typhoid bacilli in 100 c.c.

On the 24th day from the commencement of the experiment half-a-pint (about 284 c.c.) of the infected water was drunk, this quantity of water having originally contained 218,680,000 typhoid bacilli. Similar amounts were drunk with impunity on the 25th, 26th, 27th, and 28th days after the beginning of the experiment.

On Aug. 19, 1910, the experiment was repeated with a fresh sample of urine, the number of typhoid bacilli per 1 c.c. of river-water being 1650. A week later no typhoid bacilli could be found, and on the 23rd, 24th, 25th, 26th, and 27th day from the beginning half-a-pint of the infected water was drunk each day without any ill-effect (Sixth Research Report, Metrop. Water Board, Nov. 1910, p. 7).

If this drinking part of the experiment is to prove anything it would be necessary for Dr. Houston to follow it up by drinking a similar number of fresh typhoid bacilli from the same

patient and contracting the disease, for without this last act we have no certainty that Dr. Houston is susceptible to this malady, and, therefore, a fit *corpus vile* on which to make this crucial test.

Vitality of the Spirillum of Asiatic cholera in potable water.—Experiments were made by Houston with the cholera spirillum on exactly the same lines as those which he had previously adopted in the case of the typhoid bacillus in raw Thames, Lea, and New River water. The principal conclusions arrived at may be summarised as follows (4th Report on Research Work, Metrop. Water Board, June, 1909):—

(1) Cholera vibrios die very rapidly in raw Thames, Lea, and New River water as the result of storage in the laboratory. At least 99.9 p.c. perished within one week, and in none of the experiments could any cholera vibrios (recognisable as such) be found even in 100 c.c. of water 3 weeks after its infection. In more than half the experiments the results were negative by the second week.

(2) The isolation of cholera vibrios from artificially infected raw river water presents no insuperable difficulties even when the number artificially added is very small, both actually and relatively to the bacteria nominally present in the river water.

(3) On the other hand, microbes liable (after careful study) to be mistaken for true cholera vibrios were not found in comparable, but non-infected, river water samples examined under precisely similar conditions.

Thus the cholera vibrios are much more perishable in these raw river waters than are the typhoid bacilli under similar conditions.

The comparatively short duration of life of pathogenic bacteria when introduced into natural waters and more especially into surface waters, which these numerous and independent investigations establish, clearly show that the process of storage in large reservoirs must form a very important safeguard against the water-carriage of zymotic diseases. This safeguard, which is supplementary to and quite independent of that of filtration, has the great advantage of being under perfect control and much less liable to accidental disturbances than are most other methods of water-purification. It is, however, unfortunate that many reservoirs attached to water works have not been designed so as to secure the maximum advantages of storage, and their rearrangement with this object in view is generally a matter of great expense and sometimes impracticable. It is to be hoped that in future engineers will be more careful to arrange for such a circulation of the water that each particle of water entering shall remain as long as possible in the reservoir before passing out.

The influence of storage on the bacteriology of surface waters has recently been made the subject of very extended and interesting investigations by Houston in connection with the London water supply. There can be no doubt that adequate storage brings about the following beneficial changes:—

(1) Reduces the number of bacteria of all sorts.

(2) Reduces the number of bacteria capable of growing on agar at blood heat.

(3) Reduces the number of bacteria capable of growing in a bile-salt medium at blood heat.

(4) Reduces the number of coli-like microbes.

(5) Reduces the number of typical *B. coli*.

(6) Alters certain bacteriological ratios for river-waters, e.g. it reduces the number of typical *B. coli* to a proportionately greater extent than it reduces the number of bacteria of all sorts.

(7) If sufficiently prolonged, it devitalises the microbes of water-borne disease (e.g. the typhoid bacillus and the cholera vibrio).

(8) Reduces the amount of suspended matter.

(9) Reduces the amount of colour.

(10) Reduces the amount of ammoniacal nitrogen.

(11) Reduces the amount of oxygen absorbed from permanganate.

(12) Usually reduces the hardness and may reduce (or alter the quality of) the albuminoid nitrogen.

(13) Alters certain chemical ratios for river-waters; e.g. the colour results improve more than the results yielded by the permanganate test.

(14) Has a marked 'levelling' effect on the totality of water delivered to the filter-beds.

(15) Tends generally to lengthen the life of the filters (only under exceptional conditions is the contrary true).

(16) An adequately stored water is to be regarded as a 'safe' water, and the 'safety change' which has occurred in a stored water can be recognised by appropriate tests.

(17) The use of adequately stored waters renders any accidental breakdown in the filtering arrangements much less serious than might otherwise be the case.

The experimental basis for many of the above statements with regard to the benefits of storage will be found in the table on p. 416 (Houston, Annual Report, March 31, 1910, p. 52):—

Fæcal streptococci in water.—Attempts have been made to supplement the indications of fæcal contamination yielded by the presence of *B. coli*. The most recent and noteworthy of these is the examination of water for the presence of certain streptococci which are usually very abundant, sometimes even more abundant, in human fæces than is the *B. coli*. This matter has been engaging the attention of Dr. Houston since 1898, and he has (June, 1910) given a special account of the results which he has obtained.

At the outset it should be pointed out that these streptococci are not peculiar to human excreta, but are also abundantly present in those of the higher animals, many of Houston's experiments having been made with streptococci obtained from cow-dung. The study of these micro-organisms does not, therefore, at present put us in possession of that all important desideratum—a means of distinguishing between contamination due to the excrement of man and that which is due to the lower animals.

According to Houston, human fæces contain, roughly, 100,000 streptococci per 1 gm. On the other hand, in some stools streptococci are either absent or present in such small numbers relatively to those of other bacteria that search

for them is useless. Their presence in water has hitherto been ascertained by spreading 1 c.c. of the water on a Drigalski-Conradi plate, on which medium, after incubation at 37°, the streptococci give rise to very minute colonies, which can then be sub-cultivated for determination of their biochemical characters.

Of 100 different cultures of streptococci

obtained by Houston from sewage works faeces: (a) 100 produced acid in lactose and in raffinose media, and all of them clotted milk. (b) None reduced nitrates to nitrites. (c) Only four produced acid in a mannite medium. (d) 97 produced acid in a salicin medium. (e) 49 produced acid in a saccharose medium.

The grouping of these properties is best

Lea water after storage at Walthamstow Reservoirs	121	21	4	60	0	10	6	8	0	1	3					

indicated by means of a convention similar to that employed in the case of *B. coli*, in which syllables are made to represent definite biochemical reactions, thus:—

la = acid in a lactose medium.
 ma = " mannite
 mi = clot milk
 ra = acid raffinose
 sac = " saccharose
 sal = " salicin

The 100 streptococci examined may then be thus classified:—

la-mi-ra-sal . . . 49	la-ma-mi-ra-sac-sal 4
la-mi-ra-sac-sal . . 44	la-mi-ra-sac . . . 1
	la-mi-ra 2

Thus 97 p.c. clotted milk, and produced acid in lactose, raffinose, and salicin media, and of these 48 produced acid and 49 no appreciable acidity in a saccharose medium.

During the year 1909 Houston examined the raw (unfiltered and unstored) Thames, Lea, and New River waters for streptococci, employing 1 c.c. of each sample on Drigalski plates as above, with the following results:—

	No. of times streptococci were found in 1 c.c.
52 weekly samples of Thames water	13
52 weekly samples of Lea water	13
52 weekly samples of New River water	2

As regards the types of streptococci found in the above 28 samples of the 71 sub-cultures of

streptococci examined the following combinations were found:—

	Thames	Lea	New River
La-ma-mi-ra-sac-sal . . .	1	2	0
La-ma-mi-sac-sal . . .	1	3	0
La-mi-ra-sac-sal . . .	9	17	0
La-ma-sac-sal . . .	0	1	0
La-ma-mi-sac . . .	0	3	0
La-mi-sac-sal . . .	4	9	0
La-mi-ra-sac . . .	2	10	0
La-sac-sal . . .	0	1	2
La-mi-sal . . .	0	1	0
La-mi-sac . . .	2	0	0
La-ra-sac . . .	0	3	0
Total	19	50	2

The above results are especially interesting as showing that the two impurer waters (Thames and Lea) contained streptococci much more frequently than the far purer water (New River), and further, that the streptococci actually discovered in the latter were of a type more remote from that of those which are usually discovered in faeces.

Bearing in mind that, on an average, upwards of 90 p.c. of the raw Thames and Lea samples, and about 50 p.c. of the raw New River samples contain typical *B. coli* in 1 c.c. or under, whilst in only 25 p.c. of the raw Thames and Lea samples, and in only 3.8 p.c. of the raw New River samples were streptococci found, it follows that the streptococci are a far less delicate index of contamination than is the *B. coli*. The absence of streptococci in 1 c.c. of a water

cannot, therefore, be regarded as any criterion of its purity. The relative scarcity of streptococci in waters which have undoubtedly received a considerable amount of sewage matters is accounted for by the fact, established by Houston, that streptococci very rapidly die off when placed in water. This circumstance points, of course, to the presence of streptococci serving as an indication of very recent contamination.

Recent bacteriological methods applied to other processes of water purification.—From the evidence already brought forward it appears that confidence in the purification which can be effected by storage and sand-filtration, under favourable conditions, has been distinctly strengthened by the application of the more recent developments of bacteriological water examination—search for *B. coli* and other microbes more or less connected with sewage contamination.

Certain other processes of water-purification which are employed on the large scale may now be briefly considered.

Mechanical filters.—The use of mechanical filters originated in America, and their employment in our own country is becoming more and more common. Such filters are in use at Bolton, Burnley, Heywood, Edinburgh, Crewe, Gloucester, Shrewsbury, and other places in Great Britain, whilst they have also been installed in India, Japan, and some of the colonies. Space does not permit the discussion of the relative merits of the two different processes of filtration. They each possess their advantages and disadvantages; they can each be made to yield good and bad results according to the manner in which they are employed. The following results may serve as an illustration of the very high degree of purification which can be secured

PURIFICATION OF RIVER WATER BY MECHANICAL FILTERS.

	Number of bacteria in 1 c.c.				<i>B. coli</i> (typical) in			
	Gelatin at 20° C.		Carbollic gelatin at 20° C. 7 days	Bile-salt agar at 37° C. 4 days	100 c.c.	10 c.c.	1'0 c.c.	0'1 c.c.
	2 days	7 days						
Raw river water	3700	—	35	19	+	+	+	+
Ditto after passing sand filters	130	405	2	2	+	+	0	0
Ditto after further passing mechanical filters	8	33	0	0	0	0	0	0

by means of mechanical filters, which, in this instance, were employed to further purify a river water, which was being very imperfectly purified by some defective sand-filters.

Clark's process of softening.—Already in 1885 the writer showed that in softening water with lime, a very large proportion of the bacteria are carried down with the precipitated chalk, but that if the latter is allowed to stand in contact with the softened water bacteria again pass from the precipitate into the water. In the softening process this removal of bacteria may, under favourable conditions, amount to upwards of 90 p.c.

Recently the writer had occasion to deal with a chalk well water, which was causing anxiety in consequence of its frequently containing *B. coli* in rather small volumes. The most obvious and unobjectionable method of purification which suggested itself was softening with lime, inasmuch as the water contained plenty of calcium bicarbonate in solution. The following table shows the results obtained in a number of small-scale experiments in which this water was treated with lime, and sometimes with aluminoferric, and in which the softened water was sometimes decanted, sometimes filtered through paper without disturbing the precipitate ('clear filtration' in the table), and sometimes filtered after deliberately disturbing the precipitate ('turbid filtration' in the table).

A great many experiments were made in addition to those recorded below, but always with the same disappointing result, that not-

withstanding a large percentage reduction in the total number of bacteria taking place, it was only in rare cases that the *B. coli* was banished from 100 c.c. of the water by the precipitation process. It must be remembered that the demands now commonly made on a purification process with regard to the removal of *B. coli* are much more stringent than with regard to the removal of bacteria in general. Thus, should an untreated water contain 1000 bacteria per 1 c.c., if by treatment the number were reduced to 50 per 1 c.c., this would represent a purification of 95 p.c., and the water would be regarded as quite satisfactory from the point of view of the total number of bacteria present. But, if an untreated water contained the *B. coli* in 0'1 c.c., and after treatment this microbe were not present in less than 10 c.c., this would signify a removal of 99 p.c. of the *B. coli* present in the original water. But so high is the standard of purity at present often demanded in respect to freedom from *B. coli*, that the water which had thus been purified to the extent of 99 p.c. might still be regarded as of a questionable degree of purity.

Ozone treatment.—The bactericidal properties of ozone have long been demonstrated,¹ but it is only in quite recent years that it has been used on a large scale for the sterilisation of town water-supplies. In France the drinking waters

of the towns of Nice, Chartres, and Cosne are being subjected to ozone treatment, whilst a plant for the treatment of 10 million gallons of water was projected in connection with the Paris waterworks. In Germany there are installations at Paderborn, Schierstein, and Hermannstadt.

The writer has made experiments with ozone in connection with the practicability of purifying the chalk well-water to which reference has just been made above. The extraordinary efficacy of this agent will be apparent from the foregoing results obtained in experiments in which the impurities of the chalk

well-water were enormously exaggerated by the addition of 4 p.c. of polluted canal-water.

Bleaching-powder treatment.—The bactericidal action of hypochlorites, again, has been long known, and bleaching powder is one of the

oldest and commonest of disinfectants. The use of hypochlorites for the sterilisation of water-supplies was first brought into prominence in this country by Houston, who used 'Chlorox' which is an electrolysed solution of common

¹ *B. coli* found absent even in 500 c.c.

salt, for the treatment of the Lincoln water-supply during the memorable epidemic of typhoid which occurred in that city in 1904-5.¹

The writer had occasion some years ago to investigate the efficiency of the bleaching-powder treatment on a chalk well-water, the experiment being made with a large experimental plant.

From the results given above it will be seen what a high degree of purification is obtained by this simple and inexpensive method of treatment, even when extremely small quantities of bleaching-powder are added to the water.

¹ In that epidemic there were as many deaths (119) from typhoid in six months as had occurred from the same cause during the previous eighteen years.

Thus the only occasions on which *B. coli* found even in 100 c.c. of the treated water was on the first day of each of the two series of experiments and thus when the apparatus had presumably not yet been completely washed out with treated water. On several occasions even 500 c.c. of treated water was examined for *B. coli*, and this microbe was on each such occasion found to be absent even in that large volume.

Similar results have been obtained by Sims, Woodhead, Thresh, Hehner, Rideal, and others.

For the more recent experience in the chlorination of drinking water, and for a summary of many other important points, the reader

should consult Houston, *Progress in Water Purification*, Trans. Inst. of Water Engineers, 27, 1922, p. 117.

Treatment with ultra-violet light.—The known bactericidal action of the ultra-violet rays has been applied by Victor Henri to the sterilisation of water on a large scale. The rays are supplied by a Cooper-Hewitt mercury lamp. The lamp is worked with 3 ampères at 220 volts, and is placed in the bend of a semicircular trough through which the water is passed. At Marseilles the process has been tried with a plant yielding 130,000 gallons per 24 hours, and using 120 watts per 1000 gallons. The crude water always contained some *B. coli*, and the total number of bacteria varied between 30 and 300 per 1 c.c., whilst, in the treated water, *B. coli* was absent and the total number of bacteria was reduced to an average of 1 per 1 c.c. (Modern Methods of Water Purification, Don and Chisholm, London, 1911). See also W. Clemence, *Engineering*, Jan. 27 and Feb. 3, 1911.

Conclusions.—During the nearly 40 years that the systematic bacteriological examination of water has been practised an enormous amount of work has been carried out by a large number of investigators, but notwithstanding the immense multiplication of results it must be admitted that no very surprising novelties have been brought to light since the year 1895. By then all the salient features in the bacteriology of water had been mapped out, and the past 30 years have more especially been occupied in filling in countless details and in confirming over and over again what had already been broadly established.

Thus, already in the earlier period, the methods of bacteriology had been successfully applied to a determination of the value of the most varied processes of water purification natural and artificial, filtration, storage, precipitation, sedimentation, &c. It had been shown how such processes should, in the interests of public health, be continuously watched over and controlled by bacteriological examinations made at frequent intervals. Again, the vitality in water of the principal bacteria associated with water-borne zymotic disease had been investigated, and the results then obtained were substantially the same as those which have been arrived at by the most recent developments in bacteriological technique. In a word, these most recent developments in the methods of bacteriology have served to confirm and emphasise the conclusions which had been generally arrived at by the less perfect methods of the earlier period.

The all-important questions which the water-examiner has to answer are the same to-day as they have been all along: (a) has the water been contaminated with the excreta of man?; and (b) if such contamination has taken place, has the water in its subsequent history been subject to conditions which would ensure the destruction or removal of the pathogenic bacteria which may at any time be present in such human refuse?

To the first of these questions bacteriology cannot give a categorical answer even to-day, because we are not acquainted with any microbes which are absolutely characteristic of human excreta. The greatly increased facilities for the

detection and quantitative determination of the *B. coli*, however, have undoubtedly placed us in a position to ascertain readily whether and to what extent a water has been contaminated with excremental matter irrespectively of whether the latter is of human or animal origin, but it is obvious that this will not, in general, carry us very far, inasmuch as practically all surface water must be more or less so contaminated.

To the second question a similarly qualified answer, again, can be readily given. If the water is free from *B. coli* in a large volume, it may safely be concluded that *a fortiori* it is free from the typhoid bacillus in a similar volume. But should the *B. coli* be found in a small volume, it does not follow that the water may at any time be liable to contain typhoid bacilli, because the discovery of the *B. coli* does not prove that the water has been contaminated by man at all.

Thus with regard to both questions, it is obvious that we are in a much stronger position in the matter of exculpating than in that of incriminating a water. However, the inference that a water free from *B. coli* in a large volume is, therefore, necessarily a safe one, requires a slight qualification in view of the remarkable and interesting revelations which have in recent years been made with regard to what are known as 'typhoid carriers.' Some of these persons suffering from 'ambulatory typhoid' discharge typhoid bacilli in the urine, and it is thus possible that water may actually become contaminated with typhoid bacilli without at the same time receiving any *B. coli*. Although this is not likely to be of frequent occurrence, still its possibility, especially in the case of men working in wells, filter-beds, and service reservoirs, should on no account be disregarded.

Certainly one of the most important advances made in bacteriology during recent years is the careful characterisation of bacteria by means of biochemical tests, and the isolation of particular types of bacteria from such mixtures as are present in water by means of special culture-media, liquid and solid. However, until bacteriologists have agreed upon uniform tests for each particular microbe it is unavoidable that there should be much confusion and that the results obtained by different observers should be difficult to compare. Under these circumstances the interpretation of results by the individual observer is a matter of the greatest importance, and it is needless to say that unless the individual observer has a wide personal experience and a thorough knowledge of the factors affecting the purity of water-supplies of different kinds his interpretation of the results obtained will not only have little practical value but may easily lead to very serious mistakes.

Thus, whilst the outstanding achievement in bacteriological water examination during the past 25 years is the systematisation of tests for detecting the presence in water of specific bacteria, especially *B. coli*, *Streptococci*, and the spores of *B. enteritidis sporogenes*, the different possible sources of these bacteria, and their different hygienic significance according to sources, under any hard and fast application of standards based on the presence of these microbes impossible without liability to serious errors of judgment being committed.

Space has not permitted reference in detail to the spores of *B. enteritidis sporogenes*¹ as an index of faecal contamination. The figures on p. 411 show how much less abundant in faeces are these spores than is the *B. coli communis*. They do not, therefore, form such a delicate test for sewage contamination as does the *B. coli*, and their final identification is much less certain. The water-bacteriologist should, however, not neglect a search for these spores, but should regard the evidence which their presence or absence affords as supplementary to that which is furnished by the *B. coli* results.

In conclusion a word may be said with regard to the relative value of the chemical and bacteriological examination of water. At the present time it is often supposed that the chemical has been entirely superseded by the bacteriological examination, and that the chemical analysis of drinking water can be dispensed with. In reality the two methods of examination supplement each other. In those cases in which the source and general characters of a water supply are well known, the variations in purity from day to day or from week to week can undoubtedly be more satisfactorily watched by means of bacteriological examination. On the other hand, it is often desired by means of a single examination to ascertain the fitness or otherwise of a water for domestic use, and in such cases the omission of a chemical analysis may lead to an entirely erroneous opinion being formed. The ingredients detected by chemical analysis—organic matter, ammonia, nitrates, chlorides, &c.—on which an opinion as to hygienic quality is based, are all much more permanent and uniform features in the composition of the water than are the amount and the nature of the bacterial life which it may contain. The chemical analysis will, therefore, if skilfully interpreted, enable a much better idea of the potability of the water to be obtained than would be possible from a single bacteriological examination.

There are so many factors and considerations which have to be taken into account if an opinion of any real value as to the hygienic quality of water is to be formed, that no knowledge or information which can be gained either by chemical, or by bacteriological examination, or by inspection of source, or by any other available means whatsoever should be neglected.

WATER-GAS v. GAS, WATER.

WATER-GLASS. *Soluble glass* v. GLASS.

WATER-OF-AYR STONE v. WHETSTONE.

WATER-SOFTENING. Some natural waters require the use of a relatively large amount of soap to form a lather, and are characterised as 'hard' waters. They contain impurities which react with and destroy soap forming a curdy precipitate, and the generic term 'water softening' connotes all processes which remove these impurities, wholly or in part. Certain processes of water purification or treatment not falling strictly within this definition, are nevertheless so related to true water-softening processes that they are most conveniently considered here.

Effects of hardness.—Hardness renders water unsuitable for many domestic and industrial uses. In washing and scouring, hard water wastes soap and discolours fabrics by the deposition of insoluble salts; in the manufacture of worsteds and woollens it decreases the pliancy of the fabric; in tanning it deposits lime in the hides; when heated or evaporated in kettles, calorifiers, boilers, &c., it deposits scale which impairs heat transmission and increases charges for maintenance and depreciation. Bicarbonate hardness hinders the uniform dyeing of fabrics. Even ice prepared by freezing hard water is unsatisfactory, being opaque, or coloured if iron is present, and leaving a dirty sediment on melting (Behrman, J. Ind. Eng. Chem., 1921, 13, 235).

Nature of hardness.—Hardness may be caused by the presence in water of soluble salts of most metals other than the alkali metals; for example, barium chloride is occasionally found as a major impurity causing hardness. But in the great majority of cases hardness is due mainly to salts of calcium and magnesium, and to a lesser degree to salts of iron and manganese.

It is usual to recognise two types of hardness, temporary and permanent.

Temporary hardness due to bases, usually calcium but occasionally iron, present as bicarbonates, is so called because it is removed by boiling the water, whereby excess carbon dioxide is gradually expelled and the less soluble normal carbonate is precipitated. With regard to certain softening processes which depend entirely on this reaction, it is important to observe that at temperatures below 100°C. but little carbon dioxide is removed unless the water be violently agitated, and that even at 100° some 10 minutes' boiling is necessary for its complete expulsion (Paul, Boiler Chemistry, Longmans, p. 94).

Hardness due to magnesium bicarbonate, often regarded as temporary, is less affected by boiling than that due to calcium bicarbonate, normal magnesium carbonate being more soluble than calcium carbonate. On the other hand, at the temperatures attained in boilers, magnesium carbonate is hydrolysed to magnesium hydroxide, which is precipitated and may even be dehydrated to the oxide.

Permanent hardness is that which persists after boiling; it is due to the combined effect of a small quantity of residual normal carbonates and of other salts, chiefly sulphates, nitrates, and chlorides, of calcium and magnesium.

Quantitative estimate of hardness.—Originally hardness was measured and stated in terms of the number of grains of calcium carbonate per gallon of a solution equivalent to the water under test in respect of the quantity of soap required to produce a lather. Hardness corresponding to 1 grain CaCO_3 per gallon (1 part CaCO_3 in 70,000 parts of water) is described as 1 degree (Clark) of hardness. Hardness is now frequently expressed in terms of parts of CaCO_3 per 100,000 parts of water; a quantity evidently equal to $10/7 \times$ the hardness expressed in Clark degrees.

It is convenient to give here a statement (Table I) of the solubilities at about 15°C. of the chief hardening impurities, together with the equivalent concentration of calcium carbonate.

¹ Klein, Local Government Board; Medical Officer's Reports, 1897-8, 1898-9, 1901-2; Klein and Houston, *ibid.* 1899-1900; Hewlett, Trans. Jenner Institute, Series II, 76; Journ. State Medicine, 1904, 12, 102.

in grains per gallon and parts per 100,000, which, evidently, represent the maximum hardness of water which can be caused by each impurity at the ordinary temperature.

TABLE I

Impurity	Solubility. Parts per 100,000	Equivalent hardness.	
		Parts per 100,000	Degrees (Clark)
CaCO_3 } Dissolved	118	118	82.6
MgCO_3 } as bi-	3100	3675	2570
FeCO_3 } carbonates	abt. 400	345	240
CaCO_3	6.8	6.8	4.8
MgCO_3	abt. 70 ¹	83	58
CaSO_4	198.3	145.5	101.8
Ca(OH)_2	170	230	161
Mg(OH)_2	0.9	1.54	1.08

¹ The solubility of magnesium carbonate varies greatly with the pressure of carbon dioxide; the figure given is for a solution in equilibrium with carbon dioxide at about the partial pressure normally existing in the atmosphere.

Some of the solubility data are uncertain, but the table will serve to give a useful indication of the softening effect of the reactions under consideration. Thus, hardness due to calcium bicarbonate alone, which may in equilibrium with carbon dioxide at atmospheric pressure attain a maximum of 82.6 degrees, can be reduced by boiling to that due to calcium carbonate alone, viz. 4.8 degrees; whilst that due to magnesium bicarbonate which may reach a maximum of 2500 degrees under the above conditions, is, by boiling, reduced only to 58 degrees, equivalent to the solubility of magnesium carbonate.

Water softening reactions.—Temporary hardness is usually removed by the addition of lime, as originally advocated by Clark in 1841, and applied by J. H. Porter in the 'Porter-Clark' process (J. Soc. Chem. Ind. 1884, 3, 51). The chief reactions involved are:

From Table I it appears that the residual hardness in a solution saturated at 15° with calcium carbonate and magnesium hydroxide would be 5.9 degrees. In practice the reactions are not complete and it is difficult to avoid a slight excess or deficit of lime, but the minimum hardness actually attained at 15° is about 3.5

Lime precipitates as hydroxide any magnesium present as sulphate, chloride, &c., but an equivalent amount of calcium remains in solution; lime does not, of course, react with calcium salts: hence permanent hardness is unaffected by the lime treatment.

Permanent hardness due to calcium salts may be treated by addition of sodium carbonate (soda ash), which precipitates calcium as carbonate, leaving in solution sodium salts of the acidic radicals with which it was combined; thus, e.g.

The origin of this use of soda ash is obscure, but it is clear that P. A. Maignen was one of the first to employ it, as a powder with lime and steam (J. Soc. Chem. Ind. 1886, 5, 22). Sodium

carbonate also removes temporary hardness due to calcium bicarbonate:

but the method has the disadvantage of leaving sodium bicarbonate in solution and is relatively costly.

Reference to Table I shows that addition of sodium carbonate cannot reduce permanent hardness due to magnesium below the 58 degrees, due to the solubility of magnesium carbonate. Such hardness is best removed by the addition of caustic alkali, or, what is equivalent and cheaper, lime and soda ash in equivalent proportions. The reaction involved is of the type:

Should a water have only permanent hardness due to magnesium salts the use of caustic soda has the advantage of leaving no residual hardness due to calcium carbonate. In the equally unusual case where the bicarbonate hardness is exactly two-fifths of the total hardness, caustic soda alone will soften the water according to the following reactions:

Certain other reagents merit brief mention. Borax, sodium silicate, and sodium phosphate can precipitate calcium and magnesium as the relatively insoluble borates, silicates, and phosphates; the two former are common ingredients in washing powders, but none of the three is used in industrial water-softening. Barium hydroxide is an effective softening reagent, especially if the impurity in water is chiefly sulphate, but its high cost and poisonous character hinder its general use.

A suspension of barium carbonate in milk of lime has been patented as a softening reagent (H. Reiser, D. R. P. 333994, 1918) and is used in certain plants by Royle; it has the advantage of yielding a water of minimum hardness even where precise adjustment of the quantity of reagent is not attained, but is liable to acquire a coating of barium sulphate, rendering it inactive.

Permutite, or artificial zeolites, form a distinct class of water-softening reagents. They are hydrated aluminosilicates of soda, similar in composition to naturally occurring zeolites, e.g. *analcite*, $\text{Na}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 4\text{SiO}_2 \cdot 2\text{H}_2\text{O}$. Such compounds, in contact with aqueous solutions of metallic salts, enter into reversible reactions of the type:

With dilute solutions of salts of the heavier metals, such as hard water, the reaction is almost complete toward the right; with concentrated solutions of sodium salts, e.g. brine, the reverse reaction largely preponderates. The utility of such reactions in water-softening is obvious, and their application is discussed below.

Though some waters are naturally softened by percolation through strata containing

zeolites, these minerals undergo base-exchange but slowly and to a small extent. The artificial zeolites, on the other hand, undergo base-exchange readily and to a large extent, and this has been attributed by Gans to a difference in constitution of the kind indicated by the following formulae:—

Permutit was first prepared by Gans (D. R. P. 174097, 1905) by allowing alkali aluminate free from uncombined alkali to act on hydrated silicic acid, employing heat to complete the reaction. Calcium permutit is formed by treating the product with calcium chloride solution to replace soda by lime.

Numerous methods for preparing similar reagents have since been described, for details of which the patent literature must be consulted. The more important methods consist (a) in fusing together convenient ingredients to yield the desired composition, e.g. 3 kaolin, 6 quartz, and 12 soda-ash (J. D. Reidel, D. R. P. 186630, 1906; see also D. R. P. 200931, 1907); or (b) in hydrating by high pressure steam, with or without the addition of alkali, natural minerals of appropriate composition such as trass, phonolite, leucite, sodalite, &c. (Permutit Filter Co., Eng. Pat. 26094, 1910; see also, re similar hydration of Portland cement, Snelling, U.S. Pat. 1325213, 1919); or (c) in effecting base-exchange by the action of metallic salt solutions upon primary products obtained as above.

Some other base-exchange reactions deserve mention. Sodium permutit removes ammonia from water; if sodium permutit be treated with dilute acid it becomes an acid permutit, which will remove soda and produce an acid water; calcium permutit removes manganese from water. If calcium permutit be treated with a solution of a manganese salt and the resulting manganese permutit be acted upon by a solution of calcium permanganate, reactions of the following type occur:

producing a dark-coloured mass containing both lime and a highly oxidised manganese group. This is, in effect, an insoluble permanganate and can serve either to sterilise water or to eliminate any iron it may contain by precipitation as ferric hydroxide which is retained upon the surface of the filter-bed (J. D. Reidel, A.-G., Fr. Pat. 405900, 1909; R. Gans, Eng. Pat. 21184, 1909). A zeolite in which soda has been substituted by stannous oxide will reduce gold from solutions of its salts and retain it as purple of Cassius. Thus it is evident that base-exchanging reactions are known of the most diverse character and applicable to many purposes.

A number of processes have been described

in which iron is removed from water by aeration effected by allowing the water to flow down towers packed with coke, or by spraying it through nozzles. In this way the iron is oxidised to the hydroxide, which remains in colloidal solution until it is coagulated and removed by the action of the material forming the filter bed. Too much aeration is to be avoided if the water contains a relatively large proportion of lime and carbon dioxide, or the latter may be driven out of the water leaving insufficient to hold the lime in solution as bicarbonate, with the result that calcium carbonate is precipitated and blocks the pipes (Kisskalt. Gas- u. Wasserfach, 1924, 67, 3; J. Soc. Chem. Ind. 1924, 43 B. 230).

Treatment of alkaline and acid waters may be briefly considered. There is no practicable method for the removal of alkali, but various reactions, e.g. addition of calcium chloride or sulphate in the form of a strong solution or as water containing permanent hardness, will serve to convert alkali carbonate or bicarbonate to a neutral salt, but the resultant water will evidently be undesirable as a boiler feed water.

Acid waters derived from moorland catchments may dissolve lead; this tendency may be corrected either by hardening the water with lime or, better, by Thresh's method of adding sodium silicate, which removes plumbo-solvency without increasing hardness.

Artificial hardening, by addition of calcium sulphate, is practised in some cases to render a soft water supply more suitable for use in brewing.

Boiler compositions contain either or both (a) ordinary softening reagents such as lime, soda-ash, and caustic soda, and (b) organic matter, e.g. tan bark, which serves, by mere mechanical action, to prevent the formation of hard scale. Reagents of class (a) may be dismissed with the comment that they are usually dearly bought in the form of boiler compositions and that, in any case, it is unsound to perform water-softening reactions within a boiler. Materials of class (b) are evidently the lineal descendants of the dead pigs our forefathers are reputed to have put in boilers to prevent scale formation (P. G. Jackson, Boiler Feed Water, Griffin, 1919, p. 26).

If a mechanical preventive of scale is desired, undoubtedly the best is pure graphite applied as a cream with water to the clean internal surface of the boiler and subsequently introduced with the feed water at the rate of about $\frac{1}{2}$ lb. per day (Hinchley, Notes on the Economical Management of Small Boiler Plants, Proc. Chem. Eng. Group, (Soc. Chem. Ind.), 1919; but see, for a scientific investigation of the mechanical effect of linseed, Brun, J. Soc. Chem. Ind. 1919, 29, 76; R. Heuss, Zeitsch. ges. Brauw, 1918, 41, 200).

Proportions of reagents.—In the great majority of cases water is treated with a mixture of lime and soda-ash in such proportion that hardness due to bicarbonates and to magnesium is completely removed by lime, and the hardness then remaining by soda-ash. The amount of reagent required for 1000 gallons of water for each grain per gallon of the various impurities is given in Table II (Paul, Boiler Chemistry, p. 99).

If magnesium salts are to be removed as hydroxide the appropriate quantities of both lime and soda-ash should be used. Quantities of reagent calculated from the table are evidently minima, and in practice a slight excess, about 8-10 p.c., should be used, and the treated water should be faintly alkaline to phenolphthalein.

TABLE II.

Impurity (Present in a concentration of 1 grm. per gallon)	Calcium hydroxide required; lbs. per 1000 gallons	Soda-ash (Na_2CO_3) re- quired; lbs. per 1000 gallons
Free carbon dioxide.	0.260	—
CaSO_4		0.111
$\text{Ca}(\text{NO}_3)_2$		0.092
CaCl_2		0.136
MgSO_4	0.095	0.126
$\text{Mg}(\text{NO}_3)_2$	0.077	0.102
MgCl_2	0.120	0.159

Emphasis should be laid on the conclusion, following necessarily from the preceding discussion, that the nature and proportions of water-softening reagents cannot be determined simply upon data of temporary and permanent hardness; for the best results it is necessary to have a complete analysis of the water.

Purity of reagents is desirable in all water-softening processes and essential where the proportion of reagents is adjusted directly or indirectly by weighing.

Commercial *caustic lime* may be of almost any degree of purity. Some samples contain magnesia, some silica and alumina, and in all the content of real lime may vary from 100 p.c. to 70 p.c. or less by absorption of moisture. A much more reliable reagent is calcium 'hydrate,' slaked lime, which, when obtained from trustworthy sources, always contains about 70 p.c. of CaO , will not easily absorb more water, and is a fine powder, convenient for storage and use. If raw quicklime is used, each batch should be tested.

Sodium carbonate is obtainable commercially as the anhydrous salt, soda-ash, and as various hydrates, and may contain impurities such as sodium sulphate or chloride, detrimental to its use in water softening. It should be bought under guarantee or be subject to test before use.

Similarly, *caustic soda* is easily procured in a state of sufficient purity for water-softening; but it should preferably be in the form of 'flake' or powder for convenience in handling, storage, and measurement.

[In the succeeding paragraphs names given in italics in brackets, thus (*Paterson*)], are those of plants or processes which embody the feature under discussion.]

Municipal and domestic water softening and filtration is directed to the production of water free from bacterial contamination and suspended matter, free from colour and from excessive hardness. Owing to its cost, water softening of municipal supplies is practised only in exceptional cases, e.g. with Kentish waters of extreme hardness, derived from the chalk. It is usually effected by an intermittent process in which softening reagents are added to and mixed with a large bulk of water, the precipitate being separated by settlement and decantation; but some small municipal supplies are softened in

large continuous automatic plants of the usual industrial type described below.

Conversely, some large industrial supplies are treated by the intermittent process, using steam to assist solution of reagents and compressed air agitation to ensure their uniform admixture with the water under treatment (*Archbutt and Deeley*). After settlement, the treated water is drawn off by a floating syphon and carbonated by a counter-current of carbon dioxide passed through the outflow pipe (*Proc. Inst. Civ. Eng. 1898, Part 3, p. 404*). Such intermittent systems when properly controlled are probably the most accurate means available for water softening (*E. V. Chambers, J. Soc. Dyers and Colourists, 1918, 34, 240*). They necessitate considerable attention in working and require large tank space, and thus are costly, unless, as in municipal processes, large quantities of water are treated and existing reservoirs can be used.

Domestic water softening is quite commonly practised, and, unless on an unusually large scale appropriate to automatic continuous plant, is also best effected intermittently. Measured bulks of reagent powder are mixed by hand with 5-10 gallon lots of water, the precipitate is allowed to settle and the softened water is withdrawn through a filter (*Maignens*) or by slow decantation (*Wilson-Perrett 'Pukka'*).

One small plant, which may be mentioned here, softens water by heating to about 80°-90°, partly by heat-exchange with treated water, partly by direct heat, the scale being deposited in a tower upon plates removable for cleaning (*Lawrence*). This treatment effectively sterilises water (*Hatch, Proc. Inst. Civ. Eng. 1906*).

Bacteria and suspended impurities are usually removed by filtration. For small domestic supplies this is sometimes effected through porous earthenware filters under pressure, and it is clear that the 'stream-line' filter, which is capable of removing bacteria and even colour from water, could be applied to the purpose (*Hole-Shaw, Proc. Roy. Soc. 1923, 103A, 556*). Wood wool, prepared asbestos wool, cloth and sponges are sometimes employed as filtering media, but practically all large-scale water filtration is effected by beds of sand, preferably quartz sand, carefully graded and supported by a layer of gravel. Filtered water is drawn off either by supporting the gravel layer upon a perforated metal plate or by providing in that layer an effluent pipe system, provided with numerous screened orifices. Wood wool filters are cheaper to install, but the difficulty of cleaning them satisfactorily necessitates periodical renewal, the cost of which must be taken into account.

Large slow sand filters are usually cleaned by laying off units of the filter periodically and removing by hand the top layer of sand. This is continued until the sand bed is so diminished as to require renewal. Rapid sand filters of the gravity or pressure type can easily be cleaned by reversing the flow of water and agitating the sand violently. Agitation is effected in some small plants by hand, in the larger plants by compressed air or by the stream of wash-water itself. A typical illustration is the *Paterson gravity filter*, shown in Fig. 1, in which the steam-jet air-injector A forces a

of compressed air through the manifold strainer system *ss*, thus agitating and cleansing

FIG. 1.

the filter bed, whilst the dirty water is drawn off by the annular trough *r* to the water outlet *w*.

FIG. 2.

The Vickers' drifting sand filter very judiciously effects a partial cleansing of the sand before it is used for filtration, and is adaptable

gravity or pressure filtration on any scale. Fig. 2 illustrates a single unit pressure-filter. In normal operation raw water admitted by the valve *A* enters the filter at *s* and passes first through the loose mass of slowly drifting sand *c*, and then through the stationary sand-bed *b*, to the manifold *x*, and the filtered water outlet *r*. Sand is continuously extracted by the pipe system *g*, and conveyed by the pipes *hh* to the sand-washer *j*, where it is washed by the incoming raw water and a small quantity of dirty water passes away by the outlet *k*, whilst the main flow of raw water carries the cleaned sand back to the filter at *s*. Valves are provided to permit agitation and washing of the whole filter bed when necessary, the advantage of this type of filter being that, under any given conditions, the interval between such washings is much greater than with ordinary filters.

Efficient working of sand-filters depends upon the formation of a superficial film, composed of the suspended matter derived from the water, which is the effective filtering medium. Where the impurities in water are so small in amount, or of such a nature, that this film is not easily formed, filtration is frequently assisted by the previous addition of 'coagulants,' such

FIG. 3.

as aluminium sulphate. This salt, usually used in the crude form, known commercially as 'alumino-ferric,' is hydrolysed in dilute solution, especially in the presence of bicarbonates, forming aluminium hydroxide, which rapidly coagulates and carries down suspended matter otherwise unfilterable, and also, by adsorption, removes colouring matter present in the water. Precipitation is best effected in a neutral solution (hydrogen ion concentration $p_{H}7$), but is not complete even with the addition of an amount of lime equivalent to the aluminium sulphate (Hannan, Chem. Met. Eng. 1921, 24, 728; 25, 502). Similar results may be attained by the use of the clear 'aluminium hydroxide solution' produced by mixing aqueous solutions of aluminium sulphate (40 grm. in 80 c.c.) and sodium carbonate (10 grm. in 40 c.c.), which, on dilution, precipitates the hydroxide in a form which settles readily (J. W. Coxe, Met. & Chem. Eng. 1923, 29, 279).

Adjustment of the supply of coagulant is effected, in pressure filtration by control of the small acid-resisting pump which delivers it into the plant, and in gravity filtration by float-controlled valves. A typical coagulant supply gear of the latter type is illustrated in Fig. 3 (Peterson), the float *v* controlled by the head of

water at the weirs *w* actuating taper valves *vv* (shown enlarged at *(a)*) so contoured as to permit, for any flow of water, a corresponding flow of coagulant by the *ss* pipes to the trough where baffles *b* cause intimate admixture with the water.

Automatic water-softening plants.—Many types of these plants are in use, differing in the means employed to effect the fundamental operations into which water softening processes are divisible, viz. (1) preparation of reagents, (2) apportionment of reagents to water, (3) mixing, and (4) settlement and filtration to remove precipitated impurities. For the better consideration of the methods to be described, it is desirable to bear in mind the following essential features of an ideal lime-soda softening plant. Preparation of reagents must be conveniently effected, preferably by automatic means, and should be so made and used that they remain of precisely the same concentration until wholly consumed. Measurement of reagents in relation to water must be accurate over long periods and at all rates of flow, and must yet permit of ready and precise adjustment. Mixing must be speedy and thorough. The reaction tanks must be of such capacity that ample time (preferably at least 2 hours) is allowed for completion of the softening reactions before the water leaves the settling tank, and of sufficiently large cross-section to permit proper settling of the precipitate. The filter should be efficient and readily cleansed, but should only be supplementary to efficient sedimentation.

(1) *Preparation of reagents.*—Occasionally reagents are used in the form of a dry powder, usually purchased ready mixed from the manufacturers of the plant or from a firm specialising in the supply of such prepared reagents. In the great majority of cases they are applied as solutions or suspensions in water, which are commonly made by direct weighing and measurement, mixing or solution being effected, in the smaller plants by hand, and in the larger plants by mechanical stirrers or injector agitators, in a tank at ground level (see Figs. 14 and 15), from which they are pumped to a supply tank above the plant.

Sometimes lime is used in the form of clear lime-water prepared in an automatic solutioner, consisting essentially of a vertical tank, having for the whole (*Boyle*) or part (*Harris-Anderson*) of its height the form of an inverted cone (Figs. 16 and 17). By means of a pipe leading nearly to the bottom, the tank is charged from time to time with a sufficient excess of a cream of slaked lime and water, and a stream of water admitted at the apex of the cone flows upward, first agitating and dissolving the lime, and later, as the cross section of the tank increases, depositing excess lime and all impurities, so that clear saturated lime-water overflows at the top. Accumulated impurities are removed from time to time by a sludge cock. The use of saturated lime-water is attended by certain difficulties which must be recognised in order to attain good results. Owing to the small solubility of lime, a considerable proportion of the raw water, sometimes 15–25 p.c., must be by-passed to the lime solutioner, which is, therefore, of considerable capacity. Sometimes the lime, probably because it is of a lumpy character

and unsuited to the process, becomes 'coated' with carbonate and fails to maintain saturation. Lastly, in cases where the temperature of the raw water varies, care must be taken to adjust the proportion flowing to the lime solutioner, so as to compensate for the considerable variation of solubility of lime shown in Table III (Paul, *l.c.* p. 96).

TABLE III

Temperature, Fahrenheit	Calcium hydrate $\text{Ca}(\text{OH})_2$, grains per gallon
32°	132·1
40°	128·0
50°	121·7
60°	115·5
70°	110·9
80°	107·7
90°	103·6
100°	100·0

(These figures do not agree with the absolute solubility given in Tables I and II, but probably correctly represent the variation of solubility with temperature.)

FIG. 4.

One type of plant has a very ingenious solutioner to prepare automatically from solid soluble salts unsaturated solutions of any desired density (*Harris-Anderson*). It consists essentially of three coaxial tubes, 1, 2, and 3 (Fig. 4), contained in a cylindrical tank 4, forming a central chamber *A*, and three annular spaces *B*, *C*, and *D*, all intercommunicating at the bottom. Solid contained in the bucket *a*, having a gauze bottom, dissolves readily in the water in *A*, owing to gravitational convection. Fresh water, introduced at the top of the annular space *B*, mixes at the bottom

with strong solution from A, and flows up the outer space D, to the outlet C. The relatively heavy solution in D balances a greater height of water in A, and the tube 2 is set, by means of the screw and nut H, at such a height that when the density of the solution in D reaches the desired value, water begins to overflow the lip J on tube 2, and, passing down the space C, mixes with the effluent solution and maintains the desired concentration in D.

(2) *Measurement of reagents.*—The numerous methods employed fall into two broad classes.

Of the plants using *clear solutions* of lime and soda, some *prepare* either or both of these as described above, whilst some rely on the *displacement* of the proper amount of a previously prepared soda solution by the quiet inflow of a corresponding amount of water at the top of a

water required to make saturated lime-water, whilst a small cup L, of fixed size, withdraws a smaller proportion of the water to the soda solutioner, the proportion of soda added to the water being controlled by adjustment of the density of the solution as described above.

In plants using lime suspensions, with or without the addition of soda, the commonest

FIG. 5.

'displacement tank,' from the bottom of which a pipe conducts the soda solution to mix with the water under treatment (Figs. 16 and 18). In either case the raw water is divided into one large stream and two smaller streams, of the proper size to make or displace the required quantities of lime and soda solutions. This division is effected by micrometer valves in the base of a common supply tank (Boyle, Fig. 16) or by a turbo-distributor (Harris-Anderson). In this distributor (Fig. 5) a circular tank A, floating on water in B, and free to rotate under guidance by the roller bearings C on the shaft D, receives the whole supply of raw water which flows out tangentially by the orifices E, causing A to rotate: the water is thus distributed evenly over the annular trough G at all rates of flow. Radial partitions, one of which is adjustable, divide off a sector of the annulus, of such size as to separate precisely the fraction of the

FIG. 6.

measuring device is some form of tipping bucket, actuated by the main flow of water, and actuating cups or scoops which supply a definite quantity of reagent to each charge of water passing. Typical examples of this device in its simplest form occur in the Boby and Beccolegg plants, the latter being illustrated in Fig. 6, where A is the tipping bucket which, after emptying, returns to the normal position

FIG. 7.

shown, and in so doing actuates the arm carrying the chemical scoop A, which discharges into A by a channel C, and agitates the suspension in the chemical tank B by means of the stirrer E. In the Boby plant the contents of the chemical cup (Fig. 7) are variable by vertical screw adjustment of the overflow tube A. Some plants (Lassen-Hort, Paterson, Wilson-Ferris) use double tipping buckets, illustrated by the

Paterson 'Oslameter,' Fig. 8. In the Lassen-Hjort plant the tipping bucket actuates a piston valve supplying reagent.

Special devices are employed in most cases to increase accuracy and decrease wear and tear;

so float in the bucket, which releases the latter when it has a definite content of water; and is buffered by a brake-paddle and springs.

Despite such devices, all tipping buckets are noisy, and in large sizes are impracticable owing to heavy wear and tear. Therefore it is

FIG. 8.

FIG. 9.

thus in Fig. 8, it is seen that the tank has some freedom of movement before it touches the arm A operating the chemical supply gear, whilst an extension lip on the bucket enables a small addition of water finally to overturn it; and the resulting shock is diminished by the brake paddle C, and absorbed by the rubber buffer D. The Lassen-Hjort tipper has a lock, actuated by

customary in the larger plants to sub-divide the main flow of water so that the measuring gear passes but a fraction of the water, whilst the remainder operates stirring gear in the reagent tank. Fig. 9 shows the Paterson bye-pass Oslameter; a dividing plate A at the weir B takes a small fraction of the water to the tipping bucket C, and sends the remainder over the

FIG. 10.

wheel D, driving the stirrers in carrying cups X, which maintain a supply of reagent in the measuring cups X. The Wilson-Perrett plant, shown in Fig. 10, passes a large part of the raw water direct to the mixer M

by the main P, and divides the residual flow from the perforated pipes A, between a larger tipping bucket B, driving the paddles C, and a smaller bucket D actuating by wheel and chain the chemical cups X.

A plant made by Wright's Forge and Engineering Co., Ltd. (Fig. 11), passes part of the water from a distributing box A through a bucket wheel B, driving a chain elevator C, carrying chemical scoops D, dipping into the reagent tank M. Another by the same maker (Fig. 12) uses the wheel B to drive by chain and bevel gearing, G, D, a screw M working in an oil-bath which lowers the discharge pipe G in the chemical tank, and so delivers reagent in proportion to the water passing. The Kennicott proportioning gear (Fig. 13) uses a small definite proportion of the raw water to lift the float R in the regulating tank T, whereby the cord C lowers a

vertical cylinder, having a scraper to strike off the powder flush with the top (Tide and Bell).

(3) *Mixing and precipitation.*—Reagents and water usually flow together into the precipitation tank, sometimes along a channel provided with baffles (see e.g. Fig. 3), and are thereby mixed. Liquid reagent is frequently discharged into a tipping bucket as it begins to fill, and is thus agitated by and with the inflowing water, mixing being completed by the very turbulent

FIG. 11.

FIG. 12.

slotted discharge pipe F in the chemical tank, the contents of which are agitated by means of a separate water wheel.

In the foregoing plants the proportion of reagent is adjusted by altering the proportion of water passing to the measuring gear, by changing the volume of reagent added or by varying the concentration of the reagent suspension.

Certain plants use a tipping bucket or water-wheel to deliver reagent in the form of dry powder, either from a hopper (*Becco-Logg, Maignane, Bely*) or by continuous rise of a piston in a

outflow when the bucket tips. Some further mixing occurs in most plants by the relatively rapid flow of the water through the channel or pipe leading it down into the settling tank.

(4) *Clarification and filtration.*—Separation of the precipitate is always chiefly effected by settlement, during the slow passage of the water up or along the settling and reaction tank, and completed by filters. These tanks and filters determine the general form and disposition of the plant in one of two commonly occurring types, characterized as 'horizontal' and 'vertical', respectively.

A typical example of the horizontal type, the Laeson-Hjort rectangular softener, is shown in Fig. 14. Water, carrying reagents discharged

by the proportioning gear *a* already described, passes down the reaction chamber *s*, up the first settling tank *c*, and through the first

FIG. 13.

wood-wool filter *d*, overflows down channels *ee*, and passes upward through the second tank and filter, *r* and *g*, and finally overflows into

the storage tank *h*, in which a ball-cock *k* maintains a constant level by controlling the raw water supply. Sludge is removed by cocks

FIG. 14

in this operation being assisted in many plants (*Boyg, Paterson*) by hand agitators.

The vertical type is illustrated by the pattern plant shown in Fig. 15, the mode

operation of which is obvious from the preceding description. Here also a wood-wool filter is used.

Sand filters have the advantage that they

are more efficient and more easily cleaned than wood-wool filters. The Royle plant, shown in

FIG 15

Fig. 16, affords an example of their incorporation in a vertical plant, and is interesting also as

FIG. 16.

_____ an automatic washing device which
media _____ description. Raw water enters the
distribution tank 4, where the three micro

meter valves, 1, 2, and 3, pass the major portion of the water to the reaction tube *z*, a smaller portion to the lime dissolver *c*, and the smallest portion to displace soda solution in the tank *v*. These reagents mix in *z*, with the water which then rises slowly, and is clarified by settlement in *z*, and then overflows down *r* to the filter chamber *g*, passes through the sand filter *h*, rises to the tank *x*, and overflows at *l*. As sediment accumulates on *h*, the head of water in *r*, necessary to maintain the required rate of filtration, increases, and the corresponding rise of water in the outer tube *m* finally sets the syphon *o* in action and causes a heavy back-stream from *x* to flow through the filter, thoroughly agitating and cleansing the filter bed.

External independent filters have the great advantage of ready accessibility; their use is illustrated by the Harris-Anderson plant, shown in Fig. 17, where A is the turbo-distributor.

Fig. 17.

B the lime solutioner, and C the soda solutioner, already described, D is the reaction tube, E the settling tank, and F the external filter.

All the foregoing types of plant are open, and thus cannot deliver water at a pressure greater than that due to the height of the outlet above the point of application. Where it is desired to utilise a natural or forced head of water without material loss, a water-softening plant may be enclosed in the manner illustrated by the Royle's plant in Fig. 18, which differs from that of Fig. 16, in that the function of the head tank and micrometer valves in the latter is now performed by the dial cocks 1, 2, and 3, that the tops of C, D, and M are enclosed, that pumps are fitted to charge the reagents into C and D, and that the automatic washing arrangement is eliminated.

By the introduction of waste steam or hot condensates into the mixing chamber (not via the measuring gear), most of the above plants, though sometimes described as 'cold-process' plants, can be used for the hot softening of water. This is frequently advan-

as a means of conserving heat and because softener worked hot will yield water of lower hardness than one worked cold.

There are, however, a number of plants specifically designed to combine the functions of exhaust steam feed-water heating, water softening and oil elimination, of which the

FIG. 18.

shown in Fig. 19 (Royle's) is an example. Some plants rely solely upon heating to soften the water (Lawrence, Erith's Recording Heater), but usually the water is treated also with soda or lime and soda, and if necessary with aluminium sulphate (Erith's, Wright's 'Neptune,' Royle's Type E, Kennicott, Lassen-Hjort, Harris-Anderson).

In Fig. 19 the crude water supply, controlled by the ball-cock A, is distributed in B, and part taken to displace soda and aluminium sulphate solutions in C and D respectively in the usual manner. Water and soda flows down through and over a series of dished plates EE, in parallel current with exhaust steam introduced at F, via an oil-separator G, any excess steam passing to atmosphere by the pipe H. Most of the hardening impurity is deposited on the plates EE, which are easily removable for cleaning. Aluminium sulphate is added in the mixing tube at K, and the water finally passes through a settling tank L and filter M as usual.

Brief reference may here be made to much work that has been done upon the 'degassing' of boiler feed-water, as a consequence of the general recognition of the fact that dissolved oxygen is the essential active agent in the corrosion of boilers and other steam plant. Two methods have been proposed, in various forms, for its removal; depending respectively upon boiling it out at atmospheric or reduced pressure, and upon causing it to combine with iron in the form of scrap-iron, iron-manganese alloys, or couples of iron with zinc or copper (see e.g. Wehner, Eng. Pat. 7272, 1915; Wilson and Anti-Corrosive Eng. Co., U.S. Pat. 1387748, 1921, and Holle, D. R. P. 308288, 1916;

L. and C. Steinmüller, D. R. P. 320898, 1917; Hartung, D. R. P., 368645, 1916; Bailey, Morgan and Met-Vickers' Elect. Co., Eng. Pat. 194342, 1921. For a full discussion see Kastner, Proc. Inst. Mech. Eng. 1921; J. Soc. Chem. Ind. 1921, 40, T. 67).

Zeolite water-softening plants.—These plants make provision for the filtration, or, rather, percolation, of water through a bed of granular zeolite, and for the periodic regeneration of the zeolite by means of brine; they are, therefore, essentially very simple and conform to the type (United Water Softeners, Ltd.) illustrated in Fig. 20. Water enters by a meter A, and, valves 1 and 4 only being open, passes in at the top of the closed reagent tank B, down through the

FIG. 19.

bed C of zeolite, supported upon a layer of quartz sand D, and thence to the main. When the meter indicates that the apparatus has treated the maximum quantity of water (calculated with regard both to the quantity of zeolite and to the initial hardness of the water), the cocks are manipulated so as to (1)

the water wholly from the tank, (2) introduce, by means of the steam injector *s*, the proper charge of brine previously prepared in the wooden tank *g*, and (3) to drain and wash the salt from the zeolite bed. This done, cocks 1 and 4 are again opened, all other cocks being shut, and the plant again functions as a water-softener.

Comparison of soda-lime and zeolite processes.—Each process has its peculiar advantages and limitations, which broadly determine its field of use and may be summarised as follows:—

With efficient plant, properly operated, the residual hardness of treated water should be 3–5 degrees for the cold soda-lime treatment, 1–3 degrees for the same process worked hot, and 0–1 degree for the zeolite process.

Dissolved solids are diminished by lime-soda treatment, but increased by zeolite softening,

owing to the substitution of sodium salts for calcium salts.

Treatment of water containing iron or sediment presents no difficulty in the lime-soda process, as these impurities are removed with the precipitate in the normal course of working. Such waters, however, must be freed from iron and sediment before entering zeolite softeners, to avoid the formation of a deleterious coating on the active material.

Cost of plant for lime-soda treatment depends only on the maximum hourly flow of water, whilst for the zeolite process it depends also on the hardness of the water. It is also affected by the fact that stoppages for regeneration of a zeolite plant are more frequent and of greater duration than those for cleaning of a lime-soda plant.

Cost of treatment is about the same for removal

FIG. 20.

of permanent hardness by either method, but temporary hardness is removed by lime at about one quarter the cost of its removal by zeolite.

From the foregoing characteristics it appears that in the textile, dyeing, and laundry industries, where minimum hardness is the first consideration, zeolite softening is the more suitable. In many such cases, where the water contains iron or sediment, and has any considerable temporary hardness, it is advantageous to treat it first with lime in a precipitation softener and then remove residual hardness with zeolite. If this is done, ample reaction space must be provided in the lime softener, as any excess lime may hinder the operation of the zeolite softener and produce a turbid effluent.

The lime-soda process is the better for boiler-feed water, for municipal softening, and for water to be used in ice manufacture. Its suitability for municipal softening is determined by its low cost and by the possibility of applying it in existing installations. For boiler-feed and

ice manufacture reduction of dissolved solids is of primary importance, and this requirement is best met by the precipitation process. Where a raw water contains much bicarbonate hardness, the quantity of alkali bicarbonate produced by zeolite softening may cause serious alkalinity and priming in boilers. (For a fuller discussion of these matters, see Blumenthal, *Zeitsch. angew. Chem.* 1921, 34, 189; and Behrman, *J. Amer. Waterworks Assocn.* 1923, 10, 623; Memoranda by the Chief Engineer to the Manchester Steam Users' Association, 1903, and 1917–18; for a discussion with special reference to the textile industries, see King and Chambers, *J. Soc. Dyers*, 1918, 34, 240–247.)

WATER STONES v. AGATE.

WATERS, AERATED v. AERATED WATERS.

WAVELLITE. A mineral consisting of hydrous aluminium phosphate $3Al_2O_3 \cdot 2P_2O_5 \cdot 12H_2O$, forming globular or stalactitic masses with an internal radiating structure. The colour is

white, yellowish, or green; sp.gr. 2.32. The mineral usually occurs on the joint faces of slaty rock, and was first observed in the eighteenth century by Dr. W. Wavell in the slates at Filleigh near Barnstaple in Devonshire. Good specimens have also been found in Co. Cork. In larger amounts it occurs in Arkansas and Pennsylvania. At South Mountain in Pennsylvania it has been mined for use as a fertiliser and as a source of phosphorus, used locally for making matches.

L. J. S.

WAX-OPAL v. OPAL.

WAXES, ANIMAL AND VEGETABLE.

These waxes are a group of substances resembling beeswax in their physical properties; they are mixtures of compounds composed of the elements carbon, hydrogen, and oxygen. Waxes of mineral origin, such as paraffin wax, ozokerite, ceresin, and montan wax, are described elsewhere. Physically the waxes come in the series (1) fixed oils, (2) soft fats, (3) tallow-like substances and solid fats, (4) waxes, and (5) resins. The waxes all melt below 100°. The waxes differ from the fats in having little or no greasiness at ordinary temperatures. The greasiness of most of the fats is probably due to their containing some olein (glyceryl oleate) or some glyceryl esters of unsaturated fatty acids. There was an impression in the last century, doubtless produced by Chevreul's work on the fats, that whilst the fats contained glyceryl esters, the true waxes did not, but contained esters of higher members of the $C_nH_{2n}O$ series of acids with alcohol radicles other than glyceryl. As a result of this an unfortunate system was introduced of denying the name of 'wax' to those waxes that are largely composed of glycerides, and of calling them 'tallows.' It serves no useful purpose and has the effect of upsetting the ordinary meaning both of 'wax' and of 'tallow.' By it, on the one hand, Japan wax was to be called Japan tallow and myrtle wax was to be called myrica tallow, because they are both largely composed of glyceryl palmitate; and on the other hand, sperm oil was to be described as a liquid wax, because it was thought to contain very little glyceryl esters. Refined wool fat, a soft unctuous substance, was called wool wax. The inadvisability of attempting to alter the meaning of a word in common use to suit some special scientific classification was

noted out by Gregory in *Nature*, 1911, 87,

Beeswax and most of the vegetable waxes seem to be produced by the integuments of the organisms and not internally, and their value to the plant is to repel water or resist its action and prevent its ingress or egress. Beeswax, similarly, is a very suitable material of which to form the cells for storing honey, as it does not become soft or soppy by the action of the water in the honey.

The chief proximate components of the waxes are: (1) esters of the fatty acids with alcohols containing a high number of carbon atoms; (2) esters of fatty acids with glycerol; (3) free fatty acids; (4) free alcohols containing a high number of carbon atoms; (5) hydrocarbons. With respect to the formulae of compounds containing a high number of carbon atoms, it should be borne in mind that a CH_2 more or less makes such a small difference in the percentage com-

position that the exact formula cannot be settled by a carbon and hydrogen determination, and consequently authors differ somewhat in the formulae they assign to the components of the waxes; such formulae must therefore be regarded as scarcely fixed yet. Another point to be remembered is that authors have sometimes been careless, in that they have stated that substances found in the products of saponification of a wax were present in the wax; thus it has been stated that beeswax contains myricyl (melissyl) alcohol and ceryl alcohol, when the experiments only showed that these were found after saponification. There was no evidence to show that the free alcohols were present, and no doubt those found came from esters in the beeswax.

The waxes, like most natural products, are mixtures of several components, and the isolation of these is a difficult and lengthy task, which has been attempted by comparatively few investigators. In consequence of this and in order to meet the requirements of commerce, it is customary when examining samples of the waxes to determine what may be called their *analytical values*, and from the results to infer their quality and freedom from adulterations. These values are also called the *characteristics* of the waxes; they have been much studied and include the physical determinations of specific gravity, melting point and sometimes refractive index, and also certain chemical determinations, which are explained below under the heading 'Beeswax.'

It has been observed that Japan wax has the peculiarity of showing a lower specific gravity and a lower melting-point when it has recently solidified after having been melted, than when some time has elapsed since solidifying. Other waxes probably possess similar peculiarities.

Text-Books.—Benedikt-Ulzer, *Analyse der Fette und Wacharten*, Fünfte Auflage, 1908. Lewkowitch and Warburton, *Chemical Technology and Analysis of Oils, Fats and Waxes*, 6th ed. 3 vols. 1921–23. Wolff, *Die Lösungsmittel der Fette, Oele, Wachse und Harze*, 1922.

Arjun wax (*White insect wax of India*). About the year 1786 a wax produced by an insect was noticed in Madras by Dr. James Anderson (Correspondence, 1788–1791) and was called by him *White Lac*. It was thought that it might resemble the Insect wax of China, but it is distinctly different. Attention has been drawn to it from time to time, but it seems never to have been utilised. The insect producing it was first named *Coccus ceriferus*, and later *Cero-plastes ceriferus*; it has been found on the arjun or kowa tree, on poplar, mango, tea bushes, and on other trees. The crude wax occurs on the twigs in small mounds of a dull buff colour; it contains some moisture and black matter from which it can be freed by melting and straining. When thus purified it is yellow like beeswax, and hard and brittle like resin. It is partially soluble in cold alcohol, and nearly all of it dissolves in boiling alcohol; when the solution cools it becomes white and opaque. In warm ether it dissolves readily, but not completely. In hot oil of turpentine it dissolves readily, but the liquid becomes white and opaque on cooling. In benzene it is easily soluble with the exception of a little brownish matter. Carbon disulphide dissolves it only partially.

Pearson (Phil. Trans. 1794, p. 383) examined the wax from Madras and found that it melted in water at 83°. He made candles of it, but found that they smoked and gave a resinous odour.

Moore (J. Agric. Hort. Soc. of India, 1874-75, 5, 78) reported on some from Chota Nagpur, that one specimen contained 11 p.c. of moisture, another 13 p.c.; that it melted at 55°; that (probably after drying and melting) the specific gravity was 1.04, and the composition corresponded to the formula $C_{13}H_{22}O$.

Holland (Indian Museum Notes, 1891-93, 2, 93) reported on some from the Central Provinces, that it (the crude material apparently) melted at 60°, and had a specific gravity of 1.04 at 29°.

Balanophore wax occurs in the parenchymatous cells of various species of Balanophores. These are small parasitic plants growing on the roots of various other plants and are found in abundance in Java. They are so rich in wax that they burn with a bright light, and the natives prepare candles by pounding the plants to a paste and coating thin strips of bamboo with this. The wax was named *balanophorin* by Göppert in Nova Acta Acad. Caes. Leopoldinae Carolinae Nat. Curiosorum, 1841, 18 Suppl. 229, where a botanical account of the plants is given. The wax was examined by Poleck (*ibid.* 1847, 22, 117), who found that it was very soluble in ether and also that it dissolved when gently warmed with concentrated sulphuric acid and was precipitated again by dilution. It was examined more recently by Simon (Sitz. Ber. Kaiserl. Akad. Wissenschaften, Wien, 1910, 119 II. b, 1161). Air-dried slices of the plants (the latter had been preserved in alcohol) were reduced to a coarse powder and extracted with hot ether; they yielded about 65 p.c. of crude wax which, when melted and filtered (this took 4 months to accomplish), gave a honey-yellow wax, brittle when cold, but becoming soft when warmed in the hands and capable of being drawn out in fine threads. One part required about 140 parts of 95 p.c. alcohol for its solution, and of the product of this purification one part required about 50 parts of acetone for its solution. Balanophorin was thus obtained as a white amorphous powder. After further purification it was found to melt at 56°-57° to a colourless liquid resembling glycerin, which slowly solidified to a white wax. By analysis it was found to have a composition corresponding to $(C_{13}H_{22}O)_n$, just as Poleck had found. It gave no acid value nor saponification value. When strongly heated no acrolein was given off. Simon succeeded in decomposing it by distillation in a partial vacuum containing carbon dioxide, and also by fusion with potassium hydroxide, and in both cases obtained palmitic acid as a product. An account of other products was to be published later.

Langedorffia hypogaea, another of the Balanophores, which is found near Bogota, in Colombia, yields large quantities of wax, and the stems are sold in the markets and used as candles on saints' days (Hooker, Trans. Linn. Soc. 1859 22, 41). This wax does not seem to have been chemically examined yet.

Beeswax is produced by the common bee *Apis mellifica*, and also by some allied species;

it is not collected from the flowers by the bee, but is the secretion of certain organs situated on the underside of the abdomen of the neuter or working bees, and is used by them in forming the cells of the honeycomb. They are said to consume about 10 lbs. of honey in order to secrete 1 lb. of wax. To obtain the wax the honey is allowed to run out from the comb, which is then pressed to separate as much honey as possible. The adhering honey and other impurities are next removed by melting the mass in hot water; the melted wax floats on the surface, and is strained to remove dead bees and brood. The residue is put in layers with straw, and is pressed to obtain more wax, the straw acting as a filter; this product is known as 'press wax.' The mass then remaining is sometimes extracted with benzene to obtain still more wax, the product being 'extraction wax.' The 'extraction wax' is apt to be impure from the use of artificial comb, and also from substances being extracted from the dead bees and straw; further, wax compositions and adulterated beeswax are also sold under the name of 'extraction wax' (Hirschel, Chem. Zeit. 1904, 28, 212). A common practice is to pare off the capping of the honey cells and then place the comb in a centrifugal machine, which removes the honey and leaves the comb undamaged, so that it can be replaced in the hive to be refilled by the bees, and thus save the honey that they would use to produce fresh wax. In this system the capping only is melted down for wax. Impurities may be introduced into beeswax by the use of artificial combs and foundations for combs made of materials other than beeswax. These are employed to save the honey which the bees would consume in making the wax.

Beeswax is yellow in colour and varies in tint, according to the materials employed by the bees and the care taken in its preparation; sometimes it is brownish, reddish, or greenish. It has a pleasant honey-like smell, which is made more apparent by warmth. When cold it is brittle; at ordinary temperatures it is tenacious; its fracture is dry and granular.

Solubility.—It is insoluble in water. Carbon tetrachloride is said to be the best solvent. Other solvents are: chloroform, carbon disulphide, tetralin (tetrahydronaphthalene), hexanil (hexahydrophenol), benzene, benzine, oil of turpentine, ether (not a very good solvent). The solvent is to be used hot, and in the case of some or all of these, a portion of the beeswax separates on cooling.

As regards ether, Buchner (Chem. Zeit. 1907, 31, 570) allowed beeswax to soak in ether at the ordinary temperature for some time, then filtered the resulting homogeneous paste, and washed it with ether; after getting rid of the ether he obtained from the filtrate 30 p.c. of a fairly soft, deep yellow mass, and from the insoluble residue 70 p.c. of a bright brownish wax considerably harder than the original wax. The soluble portion had an acid value of 40 and a saponification value of 83.8, whilst the insoluble portion had an acid value of 11.6 and a saponification value of 99.1; thus the part that dissolves is richer in acid and colouring matter and poorer in ester than the undissolved part.

Buchner (Chem. Zeit. 1918, 42, 373) also describes the difference in analytical values of

wax obtained from press-residues by using different solvents, namely, benzine, chloroform, and carbon tetrachloride. The esters appeared to be less easily dissolved than the other components, so that light benzine removed less of them than the other solvents, and the extraction wax, when light benzine was used, appeared abnormal.

Cold alcohol dissolves scarcely any; boiling alcohol dissolves a good deal (about 15 p.c. reckoning from the acid value), leaving an undissolved residue from which something is dissolved every time the treatment with boiling alcohol is repeated. All except about 2 p.c. is deposited when the alcohol cools.

Analytical values.—The creation of a systematic plan for examining samples of beeswax is due to Becker, Hehner, and Hübl. Becker (Dingl. poly. J. 1879, 234, 79), following Köttstorfer's plan for butter (Zeitsch. anal. Chem. 1879, 18, 199), determined the saponification value. Hehner (Analyst, 1883, 8, 16) determined the amount of potassium hydroxide required to neutralise the free acid and that required to saponify the whole wax; but he expressed his results in terms of cerotic acid and myricin. Hübl (Dingl. poly. J. 1883, 249, 338) prescribed the determination of the acid value, the ester value, the ratio value, and later for fats and oils (*ibid.* 1884, 253, 281) of the iodine value. The meaning of these terms may be briefly explained as follows:—

Acid value.—This is the number of milligrams of potassium hydroxide required to neutralise the free acids in one gram of the sample.

Saponification value.—When an oil, fat, or wax is boiled with alcoholic solution of potassium hydroxide, not only is the free acid neutralised, but the esters of the various acids are decomposed, potassium taking the place of the alcoholic radicles and forming salts (soaps) with the acids and the alcoholic radicles forming the corresponding alcohols. The number of milligrams of potassium hydroxide used in effecting these two actions for one gram of sample is called the *saponification value*.

Ester value.—If the acid value is deducted from the saponification value the remainder represents the number of milligrams of potassium hydroxide that has been used in decomposing the esters, and is called the *ester value*. Esters were formerly known as compound ethers, so the term *ether value* is sometimes found instead of ester value.

Ratio value.—If the ester value is divided by the acid value, the quotient is called the *ratio value*. It is useful in deciding on the purity of a sample.

Iodine value.—In most cases the oils, fats, and waxes contain unsaturated compounds; these when treated with solution of iodine and mercuric chloride under prescribed conditions combine with a certain amount of iodine. The percentage of iodine thus taken up is called the *iodine value*; it is a measure of the amount of unsaturated compounds in the sample. It differs from the other values in being a percentage and not a number of milligrams.

Total acid number.—Benedikt and Mangold (Chem. Zeit. 1891, 15, 474) proposed a determination of what they called the *total acid number*, but it has not come into general

Instead of 'value' the term 'number' is often used for the above results.

Although these values are a useful guide in judging the purity of a sample, they are not infallible, since it has been found possible, by a judicious mixture of ingredients, to prepare composition waxes which will give the correct analytical values for a pure beeswax.

Buchner value.—To examine samples of beeswax containing such composition waxes, Buchner (Chem. Zeit. 1895, 19, 1422, corrected by Kissling, *ibid.* p. 1682, and improved by Berg, *ibid.* 1903, 27, 753 and 754. and in Benedikt-Ulzer's Anal. Fette u. Wachsarten, 1908, p. 1095) devised a determination giving what is known as the *Buchner value*. The sample is boiled with alcohol, and then after 12 hours the acidity of the liquid is determined.

Weinwurm's test.—This is a test described by Weinwurm in Chem. Zeit. 1897, 21, 519, to detect paraffin or ceresin in beeswax. It uses glycerol and is useful, but not always reliable; see various papers in the bibliography and Benedikt-Ulzer, Anal. Fette u. Wachsarten, 5th ed. 1908, p. 1109.

Long tables giving the recorded analytical values of ordinary yellow beeswax are to be found in the text-books of Benedikt-Ulzer and of Lewkowitsch and Warburton; and Buchner in Zeitsch. öffentl. Chem. 1912, 18, 90, gave the values of some abnormal waxes. Berg (Chem. Zeit. 1903, 27, 752) gives a long table of the values of various waxes. They may be summarised as follows. Some errors have been corrected by the original sources, and 'press wax' and 'extraction wax' are excluded.

	Commonly occurring values lie between	Extreme values are	
		Minimum	Maximum
Specific gravity at 15°.	0.958 to 0.967	0.949 F. (0.941 L.)	0.972 St.
Melting-point . . .	62.5° „ 66.5°	61° St. (60.5° L.)	66.5° Bg.

- L.—*Lidow*. Russian commercial samples, but it is not clear whether adulterated samples were excluded and in the sp.gr. the temperature is not stated, Chem. Zeit. Repert. 1905, 29, 278, from Westnik shirow. wesch-tsch, 1905, 6, 89.
- M.—*Masbaum*. Portuguese beeswax, Zeitsch. angew. Chem. 1903, 16, 647.

Detailed directions for ascertaining the analytical values, for performing tests, and for interpreting the results will be found in the text-books and in the original papers; they have been subjects of much controversy especially those for the saponification value, since many of the waxes are not so readily saponified as the fats.

In deciding on the purity or otherwise of a sample, all the analytical values and the results of tests for impurities must be considered together. The text-books and various original papers and experience give guidance in forming an opinion.

Composition.—The composition of beeswax has received the attention of several investigators, and some account of the leading researches is given below.

Dr. J. F. John (Chem. Tabellen der Pflanzenanalysen, 1814, p. 42) separated beeswax by means of alcohol into a soluble and an insoluble portion. These he named *cerin* and *myricin* respectively, believing them to be the same substances that he had previously obtained from the wax of *Myrica cordifolia* from Cape Colony and had so named; thus making the common mistake of early investigators of identifying compounds from different sources on quite inadequate grounds. The *cerin* and *myricin* from beeswax and from *M. cordifolia*, however, must not now be regarded as identical. The latter wax seems not to have been examined recently and probably would be found to resemble myrtle wax in its composition. In Dr. John's time it was imagined that the number of compounds present in plants and animals was far fewer than are now known, and consequently compounds were believed to be identical if they agreed in a few simple properties. This belief has given rise to some misleading names.

Brodie (Phil. Trans. 1848, Pt. 1, 147; 1849, Pt. 1, 91), using Surroy and other beeswax, found two acids in the *cerin* or portion soluble in boiling alcohol, and named the most important of them with m.p. about 78° *cerotic acid*, giving it the formula $C_{26}H_{54}O_2$; he thought that the other acid was present in the wax in very small quantities; he estimated the wax to contain 22 p.c. of *cerotic acid*. In the *myricin*, or portion nearly insoluble in boiling alcohol, he found an ester of palmitic acid with a wax alcohol $C_{26}H_{54}O$ with m.p. 85°, which he named

melissin, no doubt from *melissa*, a bee. This alcohol is now called *myricyl alcohol*, or better, *melissyl alcohol*, since myricyl is a misleading name, arising from Dr. John's mistake, and very probably there is no myricyl present in the waxes of the *Myrica* group. Brodie also found in beeswax indications of other substances.

Very thorough investigations to find the components of beeswax were made by Nafzger (Annalen, 1884, 224, 225) and Schwalb (*ibid.* 1886, 235, 106); they used Württemberg country yellow wax and employed long series of fractionations. In the part soluble in hot alcohol, the *cerin*, Nafzger found principally *cerotic acid* with m.p. 78°, for which he favoured the formula $C_{26}H_{54}O_2$, or perhaps $C_{25}H_{50}O_2$; he found also some *melissic acid* $C_{26}H_{50}O_2$ with m.p. 89°–90°, and another acid of m.p. 75°–76° in small quantity. The ester portion left undissolved by the hot alcohol, the *myricin*, was saponified, and the product was extracted with hot petroleum ether to dissolve out wax alcohols, &c., thus leaving sodium salts of the fatty acids. From these latter he obtained palmitic acid $C_{16}H_{32}O_2$ with m.p. 61.5°, and satisfied himself that they included no salts of other higher fatty acids such as *cerotic acid* or *melissic acid*. Consequently no esters of such acids are present in the *myricin*, although *cerotic* and *melissic acid* are present in the wax in the free state and are found in the *cerin*. As regards acids of the *oleic* series: from the mother liquor of the *cerin* and from a certain mother liquor obtained in the examination of the *myricin*, he obtained similar yellow acid syrups having the characteristic odour of beeswax. These he believed to contain mixtures of acids of the *oleic* series, the odour being due either to these acids or to some special substance mixed with them. Thus these acids are present both free and as esters.

Schwalb completed Nafzger's work by examining the substances extracted by petroleum ether from the saponified *myricin* and so containing the wax alcohols which had existed as esters in the original wax. In this extract he found not only wax alcohols, but hydrocarbons; the presence of which in beeswax he was the first to discover. He isolated two which he believed to be normal heptacosane $C_{27}H_{56}$ with m.p. 60.5° and normal hentriacontane $C_{31}H_{64}$ with m.p. 68°; he also obtained a soft vaseline-like mass and thinks that other lower paraffins were present. He estimated the amount of the above two in beeswax (not the total hydrocarbons) to be about 5 to 6 p.c. As regards the alcohols produced by the saponification of the *myricin*, he found *melissyl alcohol* with m.p. 85°–85.5° and from it prepared the corresponding *melissic acid* with m.p. 88.5°–89°. He favoured the formula $C_{26}H_{50}O$ for the alcohol and $C_{26}H_{50}O_2$ for the acid. He also found evidence of the presence of lower alcohols in the saponification products, so to identify them he converted the mixture containing them into the corresponding acids and drew the conclusion that one was *ceryl alcohol* $C_{26}H_{54}O$ or $C_{27}H_{56}O$, convertible into *cerotic acid* by heating with soda lime and that another was $C_{24}H_{50}O$ or $C_{25}H_{52}O$. (These alcohols, doubtless, were not present free in the wax, but were produced by the action of their esters with palmitic acid.)

Marie (Ann. Chim. 1896 [7], 7, 145) made a close examination of the product regarded by Brodie as cerotic acid. He found that fractional solution in methyl alcohol was a much better method of separation than fractional precipitation or fractional crystallisation, and that it effected separation into pure cerotic acid and a much larger proportion of melissic acid than had previously been believed to be present. He regarded cerotic acid as being $C_{31}H_{60}O_2$ or $C_{30}H_{58}O_2$ with m.p. 77.5° , the evidence pointing to the first of these formulæ; and melissic acid as being $C_{26}H_{50}O_2$ with m.p. 90° . He obtained from beeswax about 15 p.c. of the pure mixed acids, and in this he found 30–40 p.c. of melissic acid. As regards these percentages, it should be noted that in extracting the beeswax with boiling alcohol to obtain the free cerotic and melissic acids a certain amount of myricin (melissyl palmitate, &c.) dissolves too. In the treatment adopted by Marie, namely, heating the crude mixed acids with potash-lime and potash, the alcohol radicles of the myricin are converted into melissic and cerotic acids, and these are included in his percentages, although they were not present free in the beeswax. What proportion they amounted to is not clearly stated; perhaps it was not large. His object was rather to get cerotic acid than to estimate its amount in beeswax.

Schalkef (Ber. 1876, 9, 278, and 1888; 1879, 12, 696, from Russian Phys. Chem. Soc.) thinks that cerotic acid, melissic acid, and melissin are mixtures of several substances and that in cerotic acid he found an acid with m.p. 91° and formula $C_{34}H_{68}O_2$. Lipp and Casimir (J. pr. Chem. 1919, 99, 263) found in Ghedda wax an acid with this formula, but with m.p. 94.5° – 95° .

Heiduschka and Gareis (J. pr. Chem. 1919, 99, 293) have studied the question of the formulæ for melissyl alcohol and melissic acid obtained from beeswax, and of the formulæ for the similar alcohol and acid obtained from carnaüba wax. They find that the products obtained from carnaüba wax have the formulæ $C_{30}H_{61}OH$ and $C_{29}H_{58}O_2$, whilst those from beeswax contain CH_2 more and are $C_{31}H_{63}OH$ and $C_{31}H_{62}O_2$. They succeeded in preparing from the carnaüba wax alcohol the acid with an added carbon atom, and found that its lead salt was identical with that of beeswax-melissic acid. Analyses of a number of compounds that they prepared also supported these views.

The question of the total amount of hydrocarbons in beeswax can hardly be considered as settled yet. In order to determine it A. and P. Buisine (Bull. Soc. chim. 1890, [3] 3, 872 and 1891, 5, 656), using Dumas and Stas's reaction (Annalen, 1840, 35, 129), heated beeswax with potash and potash lime to 250° . In this way potassium salts of the acids are formed and the alcoholic radicles in the esters are converted into salts of the corresponding acids with evolution of hydrogen; these salts remain undissolved when the product is extracted with ether or petroleum ether, whilst the hydrocarbons go into solution. They found 12.5–14.5 p.c. and that some were unsaturated as the hydrocarbon mixture absorbed 22 p.c. of iodine. Abrams and Hett (J. Soc. Chem. Ind. 1899, 18, 591, from Zeitsch. öfentl. Chem. 5, 91), using Buisine's method, found from 12.7 to 17.5 p.c.

in different kinds of wax. Ryan and Dillon (Sci. Proc. Roy. Dublin Soc. 1916, 15, 107) found, however, that the product, supposed to be nothing but hydrocarbons, obtained from beeswax by a series of treatments, including Dumas and Stas's reaction, really contained a little oxygen; this amounted on an average to 0.8 p.c. It therefore seems that Buisine's method gives results which are too high. Ryan and Dillon suggest that some primary alcohol may be present in the product and also some secondary or tertiary alcohols; for they found that secondary and tertiary alcohols when heated with potash-lime evolve no hydrogen, and that primary alcohols do not evolve the full theoretical amount. The method thus requires further study.

The hydrocarbon, *melene*, found by Rictet and Bouvier (J. 1915, 604) in coal, in *vi*rum-tar, in Galician paraffin, and in the distillation products of beeswax, was assumed to be a solid naphthene, $C_{30}H_{60}$. J. Marcusson and F. Böttger (Ber. 1924, 57, 633) have now found that Indian paraffin wax, which melts at -60° , consists very largely of *melene*. The hydrocarbon can be readily isolated by crystallisation from benzene and then from benzine. It melts, when pure, at 62° – 63° , has $d_{20}^{20} 0.7913$; $d_{20}^{20} 0.9037$; $n_D^{20} = 1.4228$. Its composition corresponds to $C_{30}H_{60}$, and on oxidation with strong hot nitric acid, it gives a mixture of aliphatic acids, whereas naphthenes, under similar conditions, give nitro-compounds. Further, by catalytic oxidation with air in presence of manganese dioxide, *melene* yields solid fatty acids, whilst naphthenes yield polynaphthenic acids; and *melene* is slowly assimilated at 30° by *Bacterium aliphaticum*, which is incapable of attacking naphthenes. *Melene* is therefore a paraffin and not a naphthene (J. Soc. Chem. Ind. 1924, 43, B 457; cf. Funcke, Arch. Pharm. 1921, 259, 93).

In order to discover the cause of the difficulty experienced in saponifying beeswax completely Berg (Chem. Zeit. 1908, 32, 777) investigated the substances, amounting to about 2 p.c., that remain in solution after boiling beeswax in alcohol and allowing the liquid to cool, thus eliminating the crude cerotic acid and myricin. By evaporating the solution and extracting the residue thus obtained with ice-cold petroleum ether, he first separated as insoluble 0.44 p.c. of a brown semi-fluid mass having an intense beeswax odour. In the part that dissolved he found indications of various acids and then cholesterol esters, discovered by the colour test; he believes that 0.6 p.c. of these are present in beeswax, and probably considerably more. Such esters are difficult to saponify and have high saponification values. He saponified them and found cholesterols and several acids which seemed to be acetic, butyric, valeric, and others which were not volatile on the water bath, and included one that possessed the beeswax odour and was unsaturated, as its lead salt was soluble in ether. He did not succeed in making any ultimate analyses; but his work shows what a large number of compounds are contained in beeswax in minute proportions. He also examined in the same way a white wax bleached by permanganate.

Summing up the results of the various re-

searches, it appears that ordinary beeswax is composed chiefly of melissyl palmitate $C_{31}H_{63}O_2$, $C_{31}H_{61}O_2$, with some ceryl palmitate $C_{33}H_{65}O_2$, $C_{33}H_{63}O_2$, and some palmitate of the radicle $C_{16}H_{33}$; these are contained in the part known as myricin, which is very nearly insoluble in boiling alcohol. In the part known as cerin, which is soluble in boiling alcohol, there are present free acids amounting when purified to about 15 p.c. of the beeswax, chiefly cerotic acid. According to Mario, crude cerotic acid contains about 60 to 70 p.c. of cerotic acid $C_{26}H_{52}O_2$, and about 30 to 40 p.c. of melissic acid; but owing to the method he used, some of these acids may have come from decomposition of some of the myricin. There are also indications of the presence of another acid. Hydrocarbons are also present, namely, normal heptacosane $C_{27}H_{56}$, and normal hentriacontane $C_{31}H_{64}$, together amounting to 5 to 6 p.c., and in addition a soft vaseline-like mass has been separated.

Gascard and Damoy (Compt. rend. 1923, 177, 1222, 1442) state that after saponification they have obtained from beeswax the following compounds: (1) Neocerotic acid $C_{25}H_{50}O_2$ (m.p. 77.8°), the same acid that Mario described as having m.p. 77.8° and called cerotic acid. It has the same formula as Carius's hyaenic acid, but they consider that that was not a pure compound. (2) Cerotic acid $C_{27}H_{54}O_2$ (m.p. 82.5°), identical with that obtained from Chinese insect wax, and apparently identical with the acid that Tropsch and Kreutzer (Brennstoff-Chemie, 1922, 3, 49, 177) obtained from montan wax and named carbocerinic acid. (3) Montanic acid $C_{29}H_{58}O_2$ (m.p. 86.8°), apparently identical with the acid that Tropsch and Kreutzer (l.c.) obtained from montan wax and called montanic acid. (4) Melissic acid $C_{31}H_{62}O_2$ (m.p. 90°). They suggest that perhaps the acid that Brodie obtained from myricin is really not palmitic acid $C_{16}H_{32}O_2$, but one with an uneven number of carbon atoms. (5) Neoceryl alcohol $C_{29}H_{58}O$ (m.p. 75.5°). (6) Ceryl alcohol $C_{31}H_{62}O$ (m.p. 80°), identical with that from Chinese insect wax. (7) Montanyl alcohol $C_{29}H_{58}O$ (m.p. 84°). (8) Myricyl [melissyl] alcohol $C_{31}H_{64}O$ (m.p. 87°). The ceryl and melissyl alcohols were the most abundant of the alcohols. (9) Penta-cosane $C_{25}H_{52}$ (m.p. $54.5-54.6^\circ$). (10) Hepta-cosane $C_{27}H_{56}$ (m.p. $59.2-59.5^\circ$). (11) Nona-cosane $C_{29}H_{60}$ (m.p. 63.5°). (12) Hentriacontane $C_{31}H_{64}$ (m.p. $68.4-69^\circ$).

Indications have been found of many minor constituents which have not yet been fully identified: (1) The yellow colouring matter which is very soluble in alcohol. (2) The substances to which the characteristic odour of beeswax is due. (3) Unsaturated acids (their lead salts being soluble in ether), both free and as esters; the odour seems to be associated with these. (4) Various other acids. (5) Cholesterols combined as esters, perhaps with acetic, butyric, valeric, and non-volatile acids. These cholesterol esters amount to at least 0.6 p.c. of the beeswax and very probably more, and perhaps some cholesterols are also present free. (6) It has been suggested that the difficult saponification of beeswax is due to the presence of lactones as well as to the cholesterol esters, since carnauba wax is known to yield a lactone. (7) Buchner (Zeitsch. öffentl. Chem. 1910, 16, 131) says that traces of

glycerides are nearly always present in beeswaxes.

It must be remembered that a substance like beeswax is not of constant composition and that there are many circumstances likely to cause variations such as the breed of the bee and the weather of the year it was produced in. Further, Reid (J. Soc. Chem. Ind. 1915, 34, 462) points out that usually in melting the comb some of the propolis is absorbed by the wax, and that the wax from old pollen-clogged combs is different from that from new combs.

Foreign varieties of beeswax.—In addition to wax resembling European beeswax fairly closely, varieties giving very different analytical values are imported into Europe; they are products of various species of bees other than *Apis mellifica*. About 1896, samples of Indian beeswax were appearing in Germany under the name of *Ghedda wax* and were examined by Buchner; it turned out later that they were products from *Apis dorsata*, *A. indica*, and *A. florea*. He found that they gave values differing considerably from those of ordinary beeswax, although they resembled it in appearance. They were, however, brighter in colour, more plastic, and had a pleasant odour, which was especially noticeable on saponification. This Indian beeswax continued to come on the German market from Bombay. Buchner (Chem. Zeit. 1905, 29, 79) found that it was characterised by a low acid value, a high ester value, and a high ratio value; thus in 36 samples he found the acid value to range from 5.3 to 12.2, but only in four samples was it over 10. The ester value ranged from 75.2 to 111.5, the saponification value from 81.8 to 120.2, and the ratio value from 7.4 to 17.9. Wax of this description appears sometimes to have been called China wax, and may have come from Annam or French Cochinchina as well as from India. Buchner maintains that *Ghedda wax* is a true beeswax (Chem. Zeit. 1905, 29, 79 and 1906, 30, 529), so that the difference in its analytical values must be remembered when judging the purity of a beeswax.

Hooper (Agricultural Ledger of India, 1904, 11, 73) describes the species of bees found in India, and the wax and honey trade there. The wax is derived from *Apis dorsata*, *A. indica*, and *A. florea*, but chiefly from *A. dorsata*; *A. mellifica* does not occur there except as an importation. The wax from the combs of these three species seems to be substantially of the same composition. It differs from European beeswax in having a much lower acid value; in the case of 33 specimens from these three species the acid value ranged from 4.4 to 10.2, with an average of about 7, the ester value from 69.5 to 123.8, the saponification value from 75.6 to 130.5, and the Hübl iodine value from 4.3 to 11.4. The m.p. ranged from 60° to 68° . Some Indian waxes of unknown origin gave higher acid values and other values outside these limits. In the comb the upper part gives a clean white wax and the lower part a dirty and coloured substance; but as a rule these parts are not separated before melting. Turmeric is universally added to give the wax a golden yellow colour, as white wax is not appreciated in the native markets. In one district it is said that oil of *Sesamum indicum* is added.

Hooper (l.c. p. 79) also describes another kind

of beeswax produced in India and Burma by minute stingless bees of the *Melipona* or *Trigona* species, sometimes called mosquito bees or dammar bees. It is of a blackish colour and sticky consistency. In 8 specimens the acid value ranged from 16.1 to 22.9, the ester value from 55.2 to 128.3, the saponification value from 73.7 to 150, the iodine value from 30.2 to 49.6, and the m.p. from 66° to 76°.

Most probably the natives do not keep the *Melipona* wax separate, but mix it indiscriminately with the wax of the three *Apis* species.

Hooper describes (*ibid.* 1908, 9, [3] 31, Abstract in J. Soc. Chem. Ind. 1909, 28, 664) *Pwé-nyet* (black wax of Burma) obtained from the nests of *Trigona laeviceps* and possibly from those of other dammar bees; it is not always black and seems to be more of a resin than a wax.

In the old records a wax called *Andaques wax* is described as being collected by the Indians in New Grenada (now Colombia), especially by the Tamas tribe, which lives near the Rio Caqueta. It was probably the product of small *Melipona* bees. A sample was examined by Lewy (Ann. Chim. 1845, [3] 13, 453); after purifying it by treatment with boiling water he found that its m.p. was 77°, its sp.gr. at 0° was 0.917, and that it contained 81.66 p.c. of carbon and 13.55 p.c. of hydrogen. It was used locally for making candles for religious worship.

A black beeswax found in the Dutch Indies is described by Blits (Nederl. Tijdschr. Pharm. 10, 35, abstr. in J. Soc. Chem. Ind. 1898, 17, 468), and the wax of a South Brazilian bee, probably of the *Melipona* or *Trigona* species, is described by Gadamer and Hinderer (Arch. Pharm. 1917, 255, 423), who gives its composition as well as its analytical values.

Returning to the Ghedda wax, there is a long paper by Buchner and Fischer (Zeitsch. öffentl. Chem. 1913, 19, pp. 147, 170, and 188) on East Indian or Ghedda wax, and on so-called China wax, which gives 160 analyses by Buchner and 108 analyses by Schulten, of Calcutta. Further information about the beeswaxes of India and Eastern Asia is given by several papers of Fischer (*ibid.* for 1913 and 1914). Recently 23 samples of comb and beeswax from Bengal and Assam, collected under the supervision of District Officers, were examined at the Imperial Institute by Roberts and Islip (Analyst, 1922, 46, 246); they found that neither *Weinwurm's* test nor that of Salamon and Scaber could be relied on.

The composition of Ghedda wax or East Indian beeswax has been investigated by Lipp, with Kuhn, Kovács, and Casimir (J. pr. Chem. 1912, 86, 184; 1919, 99, 243, and 256). They found that the principal components are: one of the ceryl hydroxymargarates

ceryl margarate $C_{25}H_{52} \cdot C_{17}H_{35}O_2$, and ceryl palmitate $C_{25}H_{52} \cdot C_{15}H_{31}O_2$; together with roughly 7 p.c. of hydrocarbons, namely: heptacosane $C_{27}H_{56}$ (roughly 5 p.c.), hentriacontane $C_{31}H_{62}$ (roughly 2 p.c.), and indications of another hydrocarbon which they could not isolate. As in European beeswax, they found some free acids, but only in small proportions, namely, cerotic acid $C_{26}H_{52}O_2$, and an acid $C_{24}H_{48}O_2$, which they named *Ghedda acid*. Its m.p. was 94.5°-95°.

An acid with this formula and m.p. 91° was described by Schalfée (Ber. 1876, 9, 278, and 1888). These two acids are present chiefly in the free state and the other acids as ceryl esters. In the products of hydrolysis they found also, but only in small proportion, a different hydroxymargaric acid and traces of formic, acetic, and butyric acids and of a resinous substance.

White or bleached beeswax.—Most beeswax is bleached before use; bleached beeswax is harder, and candles made from it burn better than those made of yellow beeswax. The bleaching is effected by exposure to light and air or by chemical agents, or by both methods. Chemical agents do not bleach it so thoroughly as does light, so that when they are used a bleaching by light is required to get the results; they serve, however, to shorten the time taken in bleaching.

The wax is first purified by repeated meltings in hot water until it is no longer grey, and the remaining honey is removed. In doing this grey underlayer is cut or scraped off from cooled cake of wax, and is remelted with the next lot treated. If the water used is hard, it is stated (Cheshire, Bees and Bee-Keeping, p. 589) that the cerotic acid of the wax forms an insoluble calcium soap, appearing as a grey spongy material and that thus a waste of wax is occasioned. Rain-water or distilled water should therefore be used, or else the water should be acidified with sulphuric acid. The use of acidified water also checks the formation of emulsions and is recommended for the various remeltings. Old and dirty combs should be soaked in cold water for some time before melting, as the dirt and cocoon skins when wet do not absorb and waste wax as they would if dry.

In order to expose as much surface as possible to the sun's rays, the wax is reduced to thin bands. The melted wax is poured into a box of metal plate, in the bottom of which are several narrow slits or holes. These are directly over a horizontal wooden roller revolving in a vessel containing cold water, which covers half the roller. The wax escapes from the slits in bands, which pass on to the revolving roller and solidify in the water in the form of thin ribbons. These ribbons are removed from the water, spread on canvas stretched over wooden frames, and exposed to the sun; they are sprinkled from time to time with water to keep them moist, and turned over to expose fresh surfaces to the sun. If the sunshine is very powerful, the heat may cause the ribbons to stick together; this can be avoided by watering, but not more than is necessary should be employed, as Heinz (Seifensieder Zeitung, 1913, 40, 1140) thinks that evaporating water vapour checks the oxidising action of the air. The inner portion of the ribbon bleaches more slowly than the outer surface, so to accelerate the bleaching the partially bleached wax is remelted and again made into ribbons, so that new surfaces are exposed; this remelting, however, causes some loss. Wax from different sources bleaches with varying facility, and some varieties cannot be bleached, so samples should first be tried on a small scale.

The addition of a little oil of turpentine to the yellow wax before making it into ribbons reduces the time taken in bleaching, but is said

by Heins to impart an unpleasant odour to the wax. Rectified oil of turpentine free from resin should be used. The bleaching effect of oil of turpentine was noticed by Ostermaier (Repert. f. d. Pharm. 1834, 48, 97). Sometimes a few p.c. of tallow are added to the wax to hasten the bleaching and to diminish brittleness, and this is considered allowable and is not counted as an adulteration.

After a longer or shorter period, depending on the intensity of the sunshine and the temperature, the bleaching is complete; it takes from 10 to 60 days. The wax is then once more melted in hot water, strained, and allowed to solidify in suitable shapes.

When chemical agents are used a mixture of potassium dichromate and sulphuric acid is said to be the best (Heinz, Seifensieder Zeitung, 1913, 40, 1140, 1169, and 1192). The wax is boiled with a solution containing 12 parts of potassium dichromate and 35 parts of sulphuric acid to 100 parts of water and wax. The green chromium compound produced by the reduction of the dichromate is removed by washing the wax with water containing 6-8 p.c. of lactic acid, or containing sulphuric acid. This process has been found effective even with some waxes that were considered unbleachable.

Potassium permanganate solution, followed by sulphurous acid has been tried, but the results were not very satisfactory. Other chemical agents that have been tried or recommended are the use of artificially made ozone, of hydrogen peroxide acidified with sulphuric acid, of barium peroxide of potassium chlorate with sulphuric acid, of a liquid prepared from bleaching powder and soda. The formation of chlorine compounds in the wax is objectionable, however, as hydrochloric acid is liberated when the wax is burnt. Whenever chemicals are used they should be thoroughly washed out of the wax when the bleaching is accomplished.

Another proposed way of decolorizing beeswax is by the use of agents that absorb the colouring matters, such as animal charcoal, fuller's earth, and the like.

The theory of bleaching and the effect of various methods and also the effect of the addition of a little tallow to the yellow wax have been studied by A. and P. Buisine (Compt. rend. 1891, 112, 738, and Bull. Soc. chim. 1890, [3] 4, 465); they found that light is necessary, since, in the dark, yellow wax is not bleached when kept in a current of air or of oxygen or of ozonised oxygen, whilst in sunlight it is bleached even when kept in carbon dioxide or nitrogen or in a vacuum, though much more slowly than in air. In oxygen it bleaches more rapidly than in air, and very rapidly in ozonised oxygen. They noticed that in air-bleaching the colour does not decrease uniformly, but that white spots are seen which increase in size. They think that the colouring matter undergoes total combustion and that the oxidation of the unsaturated hydrocarbons and unsaturated acids induce this combustion, and that is why the addition of tallow, which contains olein, helps the bleaching. Oil of turpentine acts in the same way because it undergoes oxidation. They think it probable that these substances when undergoing oxidation in the light give rise to ozone, and that this under the influence of light burns up the colour-

ing matter; it being known that oil of turpentine exposed to air and light produces ozone, and that tallow, whilst turning rancid, gives an odour like ozone. They found in most cases that the m.p., the acid value, and the saponification value are increased, and that the iodine value and the percentage of hydrocarbons are lowered; decolorizing by animal charcoal, however, caused little change in the values.

Berg (Chem. Zeit. 1902, 26, 605) also records many experiments on the subject; he finds that the acid value is raised and the ratio value consequently lowered, which should be borne in mind when examining a white wax for admixtures. It is not easy, however, to draw general conclusions from his results. In Chem. Zeit. 1903, 27, 754, and 1908, 32, 778, he again treats of white wax.

Medicus and Wellenstein (Zeitsch. Nahr. Genussm. 1902, 5, 1092) examined the bleaching action of potassium chromate and sulphuric acid; they found: (1) that the acid value and the saponification value were considerably increased, but that the ester value was unaltered; (2) that the m.p. was raised 1°; (3) that the characteristic odour of yellow wax was destroyed or volatilised; (4) that no stearic acid could be found by the Fehling-Röttger test either before or after bleaching; (5) that the ester value of some myricin prepared from yellow wax was only slightly increased by bleaching.

Bibliography.—A very full bibliography for the years 1848 to 1891 is given in the U.S. Dept. Agric. Div. Chem. Bull. 13, Pt. 6, 1892, with an account of the contents of many of the papers. An abstract of this is given in J. Soc. Chem. Ind. 1892, 11, 756. The following are papers of 1892 and after, with a few earlier ones. A. and P. Buisine (Bull. Soc. chim. 1890, [3] 3, 867), methods of examination, including determination of the hydrocarbons and of the hydrogen evolved by Dumas and Stas's reaction. Kossel, Obermüller, and Krüger (Zeitsch. Physiol. Chem. 1890, 14, 599; 1891, 15, 321; 1892, 16, 152), use of sodium alcoholate or of metallic sodium for saponifying. Antoushevich (J. Soc. Chem. Ind. 1891, 10, 1014, from J. Russ. Chem. Soc. 1891, 23, 223), analyses of Russian waxes and method of analysis. Forde (Consular Report No. 1304 for Morocco for 1892, p. 17), adulteration with low-class paraffin from candles. Röttger (Chem. Zeit. 1892, 16, 1837), methods of analysis, criticism of Benedikt and Mangold's method. Buchner (*ibid.*, p. 1922), methods of analysis. Benedikt (*ibid.*, p. 1922), defence of Benedikt and Mangold's method. Marie (Bull. Soc. chim. 1892 [3] 7, 111), bromoacetic acid. Gascard (J. Pharm. Chim. 1893, [5] 28, 49), myricyl (melissyl) alcohol from beeswax, carnauba wax and gum-lac, and its derivatives. Buchner (Chem. Zeit. 1893, 17, 918), criticism of Hübl's method, and some extra tests recommended. Kehler (J. Franklin Inst. 1894, 137, 58), detection of adulterants. Parry and Estcourt (Year Book of Pharm. 1893, 370 and Chem. and Druggist, 1894, 45, 645, and 693), adulterants and their detection. Kromer (Chem. Zeit. Repert. 1895, 19, 289, from Pharm. Zeitsch. Russl. 1895, 34, 529), composition of the oil obtained by the dry distillation of beeswax and used as a remedy. Buchner (Chem. Zeit. 1895, 19, 1422), artificial compositions giving the same

analytical values as beeswax and used as adulterants; method for roughly estimating the amount of adulterant by determining a value afterwards known as the Buchner number. (For some additional directions, see Benedikt-Ulzer's book, 5th ed. 1908, p. 1095.) Buchner's method of calculation was wrong, see the next paper. Kissling (*ibid.* p. 1682), correction of Buchner's method of calculation in the previous paper. Henriques (Zeitsch. angew. Chem. 1895, 721 and 1896, 221), method of finding the saponification value, using petrol-ether or for waxes petrol-benzin as the solvent, and saponifying in the cold with alcoholic sodium hydroxide solution. Marie (Bull. Soc. chim. 1894 [3] 11, 908 and Ann. Chim. 1896, [7] 7, 145-250), the latter is a long paper on cerotic and melissic acids from beeswax, on their separation from one another by fractional solution in methyl alcohol and on their derivatives. Rambow (Chem. Zeit. 1896, 20, 1004), circumstances and processes favouring bleaching. Lugowsky (J. Pharm. Chim. 1897, [6] 5, 295, from Pharm. Zeitsch. f. Russland, 1896, 35, 839), detection of Japan wax and tallow in beeswax. Blarez (Revue internat. des falsifications, 1897, 10, 161), ceresinometer. Weinwurm (Chem. Zeit. 1897, 21, 519), Weinwurm's test for ceresin and paraffin, also his way of carrying out saponification; [but see the next paper]. [Note: Several authors say that Weinwurm's test is not trustworthy]. Henriques (Chem. Rev. Fett. u. Harz-Ind. 1897, 4, 195), a variation in Weinwurm's test [but see the next reference] and an objection to Weinwurm's way of saponifying, and also to the test being applicable for the detection of resin. Henriques (Chem. Cent. 1897, ii. 647, from Zeitsch. öfentl. Chem. 1897, 3, 274), a modification of Weinwurm's test. Henriques later stated that this modification was unreliable and warned against its use, see Lunge, Chem. tech. Untersuchungsmethoden, 1900, 4th. ed. vol. 3, p. 151. Dieterich (Chem. Rev. Fett. u. Harz-Ind. 1897, 4, 259), finds that Henriques' cold saponification gives lower values than Hübl's hot saponification. Henriques, in a note, says that he has not found this lowness. Dieterich (Helfenberger Annalen, 1897, 218), numerous analyses comparing cold with hot saponification. Buchner (J. Soc. Chem. Ind. 1898, 17, 383, from Zeitsch. öfentl. Chem. 1897, 3, 570), analyses of Indian waxes and of waxes called Chinese [probably incorrectly] giving values different from ordinary beeswax, and on the cold saponification method. Guyer (Pharm. J. 1897, 58, 308), iodine values of English beeswax. Woy (Chem. Cent. 1897, i. 565, from Zeitsch. öfentl. Chem. 1897, 3, 15), difficulty of saponifying overcome by using Müller's extractor. Beythien (Chem. Rev. Fett-u. Harz-Ind. 1898, 5, 16, from Pharm. Centralhalle, 1897, 38, 850), use of sodium ethylate for saponifying; also a comment by Henriques. Blits (J. Soc. Chem. Ind. 1898, 17, 468, from Nederl. Tijdschr. Pharm. 10, 35), black beeswax from the Dutch Indies. Werder (Chem. Zeit. 1898, 22, 38 and 59), use of refractometer for beeswax and other waxes with table of results. Dieterich (*ibid.* p. 729), a number of iodine values, and effect of various adulterants on the various analytical values, also on solubility in chloroform as a criterion. Henriques (Zeitsch. anal. Chem. 1898, 37, 699,

from Zeitsch. öfentl. Chem. 1898, 4, 416), duration for cold saponification. Kayser (J. Soc. Chem. Ind. 1898, 18, 152, from Zeitsch. öfentl. Chem. 1898, 4, 833), analytical values of Morocco beeswax. Funaro (Chem. Cent. 1899, ii. 404, from L'Orosi, 22, 109), analytical values of Italian beeswax and methods of finding adulterants. Ahrens and Hett (Chem. Cent. 1899, i. 952, from Zeitsch. öfentl. Chem. 1899, 5, 91), determination of hydrocarbons in beeswax and their amount. Lewkowitsch (Analyst, 1899, 24, 319), on the acetyl value. Chersheffsky (Chem. Zeit. 1899, 23, 597), electrical melting-point apparatus. Dlusski (Chem. Zeit. Repert, 1900, 24, 30, from Farmazett, 1899, 7, 1307), finding ceresin and paraffin by Hübl's saponification, and on the wax got from bees. Werder (Chem. Zeit. 1900, 24, 967), necessary for saponification and method detecting adulterants. Dieterich (*ibid.* p. 91), time necessary for saponification. Eichhor (Zeitsch. anal. Chem. 1900, 39, 640), use of amyl alcohol to surmount the difficulty in saponifying and to determine the acid value. Hett and Ahrens (Zeitsch. angew. Chem. 1900, 152), directions for analysis and results from beeswax from various countries. Buchner (Oil World, 1900, 1, 36), particulars and uses.

In this Century.—Buchner (Chem. Zeit. 1901, 25, 21 and 37), methods for determining analytical values and for detecting adulterants; results for ordinary beeswax, Indian Ghedda wax, African beeswax and bleached wax. Greshoff and Sack (Rec. trav. chim. 1901, 20, 73), products of the dry distillation of beeswax. Jean (Ann. Chim. anal. 1901, 6, 447), examination for resin and other adulterants. Marpmann (Chem. Rev. Fett-u. Harz-Ind. 1901, 8, 65), refractive indexes as a means of examining waxes. Davis (J. Amer. Chem. Soc. 1901, 23, 487), method to avoid spitting when estimating water. Berg (Chem. Zeit. 1902, 26, 310), rye-meal found in a sample. Dieterich (*ibid.* p. 554), adulterated Turkish samples. Berg (*ibid.* p. 605), effect of bleaching on the analytical values. Medicus and Wellenstein (Zeitsch. Nahr. Genussm. 1902, 5, 1092), effect of bleaching by chromate on the analytical values and on the components of beeswax. Mastbaum (Zeitsch. angew. Chem. 1902, 15, 929), a specific gravity bottle for use in boiling water. Reid (J. Soc. Arts, 1903, 51, 522), separating the honey from the comb. Berg (Chem. Zeit. 1903, 27, 752), analytical values of numerous samples and methods employed. Dieterich (*ibid.* p. 808), controversy on Berg's paper, on time necessary for iodine value determination, and on Storch's test for colophony. Berg (*ibid.* p. 986), a reply to Dieterich. Mastbaum (Zeitsch. angew. Chem. 1903, 16, 647), beeswax of Portugal and its colonies, statistics, analytical methods and results. Hirschel (Chem. Zeit. 1904, 28, 213), preparation and analytical values of 'extraction beeswax.' Löwy (*ibid.* p. 348), criticism of the preceding paper. Hirschel (*ibid.* p. 480), reply. Lemaire (J. Soc. Chem. Ind. 1904, 23, 840, from Bull. Soc. Pharm. de Bordeaux, 1904, 44, 182), detection of artificial colouring matter. Hooper (Agric. Ledger of India, 1904, Entom. Series, 11, 73), wax from various species of Indian bees, sources, preparation and analytical values. Cohn (Zeitsch. öfentl. Chem. 1904, 10, 404 and

415), time and method for saponification, with a discussion. Schwarz (*ibid.* 1905, 11, 6), combating Cohn. Cohn (*ibid.* p. 58), reply. Schwarz (*ibid.* p. 301), reply. Dieterich (Chem. Rev. Fett-u. Harz-Ind. 1905, 12, 79), comment on Schwarz's way of doing cold saponification. Schwarz (*ibid.* p. 132), reply. Buchner and Wirth (Chem. Zeit. 1905, 29, 32), improvements in saponification method; use of amyl alcohol; beeswax may vary in its composition; effect of bleaching; and on Indian (Ghedda) wax. Buchner (*ibid.* p. 79), origin and analytical values of Indian (Ghedda) beeswax and of dammar wax. Rakusin (J. Chem. Soc. 1905, ii, 303, from J. Russ. Phys. Chem. Soc. 1905, 37, 83), apparatus for finding specific gravity of waxes. Sokoloff (J. Chem. Soc. 1906, ii, 206, from J. Russ. Phys. Chem. Soc. 1905, 37, 818), heat of combustion of beeswax from various places and of *Trigona melipona* wax; detection of paraffin or ceresin. Lidow (Chem. Zeit. Repert. 1905, 29, 278, from Westnikshrow. wechsch. 1905, 6, 89), analytical values of Russian and other commercial samples. Buchner (Chem. Zeit. 1906, 30, 528), a claim that Indian (Ghedda) beeswax should be regarded as a true beeswax. Bollier (Ann. Chim. anal. 1906, 11, 366), analytical values of a beeswax from Annam. Bohrisch and Richter (Pharm. Centralhalle, 1906, 47, 201, 227, 270, 299, 311), a long paper on the examination of yellow beeswax. Bohrisch (*ibid.* p. 1065), recommendations for tests in Deutsches Arzneibuch. Buchner (Chem. Zeit. 1907, 31, 126), criticism of Bohrisch on saponifying. Bohrisch (*ibid.* p. 191), reply. Buchner (*ibid.* p. 270), reply. Bohrisch (*ibid.* p. 351), reply. Berg (*ibid.* p. 537), various kinds of beeswax require various times for saponifying and the cause. Buchner (*ibid.* p. 631), reply, Berg heats too gently. Berg (*ibid.* p. 705), reply. Buchner (*ibid.* p. 1085), experiments on the time for saponifying. Buchner (*ibid.* p. 570), analytical values of portions dissolved and undissolved by cold ether. Dieterich (*ibid.* p. 987), analytical values of beeswax of 0 to 5 years standing in the hive and on propolis. Berg (Chem. Zeit. 1908, 32, 777), a long paper on the minor components, the effect of bleaching, and on the detection of stearic acid. Glikin (Ber. 1908, 41, 910), iron found qualitatively. Cowan, Wax Craft, publ. Sampson Low, 1908; production, manufacture, adulterants and uses. Ryan (Proc. Roy. Dublin Soc. 1909-10, 12, 210), determining the composition of a mixed wax; analytical values of beeswax from various places. Ostrogovich and Petrisor (abstract in J. Soc. Chem. Ind. 1909, 28, 1094), detection of tallow. Le Naour (Ann. Chim. anal. 1909, 14, 369), criticism of French Codex test for adulterants. Hooper (Agric. Ledger [of India], 1908-9, [3] 31), analytical values of Burmese Pwé-nyet, the wax of *Trigona laviceps*. Stoeber (Chem. Zeit. 1909, 33, 1275), use of flash-point in examining beeswax. Buchner (Zeitsch. öffentl. Chem. 1910, 16, 123), how the wax is formed in the bee's body; abnormal East African beeswax. Imp. Inst. Bull. 1910, 8, 23, various methods of preparation; analytical values of various African samples. Pinkus (Chem. Zeit. 1910, 34, 277), the last of Flora controversy. Malfatti (Zeitsch. anal. Chem. 1911, 50, 693), on the same subject, and that asafetida was perhaps used in the 15th century, to give a beeswax odour. Sundwik (Zeitsch. physiol. Chem. 1911, 72, 455), alcohols of *pylla* wax and of beeswax compared. Winkler (Zeitsch. angew. Chem. 1911, 24, 636), use of propyl alcohol solutions for finding saponification and acid values. Wichmann (J. Chem. Soc. 1911, ii, 550, from Pharm. Zentralhalle, 1911, 52, 363), saponifying by heat and pressure. Imp. Inst. Bull. 1911, 9, 236, analytical values of various African samples; a caution about *Weinwurm*'s test. Buchner (Zeitsch. öffentl. Chem. 1911, 17, 225), behaviour of ordinary and foreign samples, pure and adulterated, with certain extra tests; on *Weinwurm*'s test; on glycerides in pure beeswax. Buchner (*ibid.* p. 311), a mistake in Deutsches Arzneibuch of 1910. Buchner (*ibid.* 1912, 18, 90), on some abnormal samples. By an application of Denigès' methylglyoxal test (Bull. Soc. Pharm. Bordeaux, 1896), P. Bourret (Bull. Soc. chim. 1924, 35, 421) has shown that pure beeswax gives no glycerol on saponification. A positive reaction therefore indicates adulteration. White beeswax often gives a positive test for glycerol, owing to the addition of tallow to the wax before bleaching. The test is carried out as follows: 2-3 grm. of the wax are saponified with 10-15 c.c. of potassium hydroxide solution for 1 hour. After dilution with 15 c.c. of water, the mixture is slowly acidified with dilute sulphuric acid (1:4) and filtered; 2 c.c. of the filtrate are treated with 20 c.c. of saturated bromine water till colourless, and 2 c.c. of this solution are treated with 0.1 c.c. of alcoholic solution of codeine and 5 c.c. of pure sulphuric acid (*d.* 1.84). After shaking and heating on a boiling water bath for 2 minutes, a fine greenish-blue coloration develops if glycerol is present; 1 p.c. of a glyceride can easily be detected in beeswax by this test (J. Soc. Chem. Ind. 1924, 43, B. 431). Lipp and Kuhn (J. pr. Chem. 1912, 86, 184), composition of Indian (Ghedda) beeswax. Mastbaum (Chem. Rev. Fett-u. Harz-Ind. 1912, 19, 232 and 260), beeswax of Portugal and its colonies; method of examining. Prettner (Prometheus, 1912, 23, 341), origin, preparation, uses, and adulterants. Leys (J. Pharm. Mailhe (Compt. rend. 1924, 179, 184), distillation of beeswax with $MgCl_2$.

Candelilla wax is obtained from plants growing wild in great quantities in the dry and desert-like districts of northern Mexico and the southern parts of the United States; they are called 'candelilla' by the Mexicans. It is a recent addition to the waxes in commercial use, attention having been called to the wax on these plants by Sanders in 1905. *Euphorbia cerifera* (Alcooc), *E. antispyphilica* (Zucc.), and *Pedicularis Peronis* (Boiss.) have been given as the plants from which the wax is obtained.

It occurs as an excretion covering all parts of

the plant, except the roots. It can be obtained by boiling the plants with water and skimming off the layer of melted wax; the pieces of plant must be kept from rising by enclosing them in wire cloth or by tying them in bundles and weighting these down. In practice a little sulphuric acid is added to the water when first obtaining the wax, and also when remelting; its action is probably to prevent the formation of an emulsion. Another plan is to subject the plant in suitable containers to live steam, which melts off the wax, and this can be easily separated from the condensed water. It is said that this plan gives a better yield, but that the wax appears softer and contains more water than that obtained by simply boiling out the wax from the plant. The wax can be purified by remelting and straining off plant debris. The yield of wax is from 1 to 5 p.c. In 1918 there were about twenty-five factories producing the wax in the Monterey district.

The wax is hard and brittle, and can be broken down to a powder at low temperatures; when full of air bubbles and water it is opaque and greyish-yellow in colour, but if these are got rid of by melting it is dark brown and translucent. When heated it gives off an aromatic odour. It is only slightly soluble in alcohol, ether, acetone, chloroform, carbon disulphide, gasoline, and oil of turpentine when cold, but is readily soluble in all these when hot; a boiling mixture of three parts absolute alcohol and two parts of 90 p.c. benzene was found to be an excellent solvent. On cooling these solutions become pomade-like masses.

The analytical values that have been recorded vary widely; this may be due to the age of the plant, the time of year at which it was gathered, the mode of preparation, the presence of water in the sample examined, the method of analysis, or even to adulteration. The following are the lowest and highest values found in the literature of the wax: m.p. 65° to 92°; sp.gr. 0.936 to 0.998; acid value 0.03 to 24; saponification value 35 to 104; iodine value 5.2 to 57.6; unsaponifiable matter 65 to 91.2 p.c. There are also variable amounts of dirt, water, and ash. These analytical values vary so much that it may be well to add those of the following authors.

Sanders (Chem. Soc. Proc. 1911, 27, 250) states that a sample of wax prepared in January from plants collected in Coahuila was greenish-white, and contained a considerable proportion of water. When freed from this it was dark brown and gave the following values: m.p. 67.5°; sp.gr. 0.9850; acid value 14.36; saponification value 46.76; iodine value (Hübl) 16.60; unsaponifiable matter 77.00 p.c.; and hydrocarbons 48.60 p.c.; he found hentriacontane and melissyl alcohol (whether free or as ester is not stated).

Lüdecke (Seifensieder Zeit. 1912, 39, 829) gives as normal values: m.p. 68-70° 0.950-0.990; acid value 13-18; saponification value 50-60; iodine value 15-20; unsaponifiable matter 65-75 p.c.; moisture 2 to and dirt 0 to 3 p.c.

Berg (Chem. Zeit. 1914, 38, 1162) gives for a grey crude wax: m.p. 80-88°; acid value 9.8; ester value 44.0; saponification value 53.6; and as the mean of two samples of brown wax: m.p. 68.5°; sp.gr. at 15°/15° 0.986; acid value

11.6; ester value 51.5; saponification value 63.1; iodine value (Wijs) 57.6 after 19 hours standing, 14.5 after 3 hours; unsaponifiable matter 67.5 p.c. Both Berg and Lüdecke used xylene when saponifying.

Composition.—Candelilla wax is remarkable among the waxes for the high proportion of hydrocarbons that it contains, but as in the case of its analytical values the results of investigations as to its composition are discordant. Sanders, in *Anal. Inst. Med. Nacional, Mexico*, for Oct. 1907, recorded the presence of hentriacontane (*J. Ind. Eng. Chem.* 1911, 3, 115). Fraps and Rather (*ibid.* 1910, 2, 454) found hentriacontane with m.p. 68°, and indications of another hydrocarbon with m.p. 85°, and of other substances.

Meyer and Soyka (*Monatsh.* 1913, 34, 1159) found that it contained resin amounting to 18 to 20 p.c., to this they attribute the acid value and the iodine value. They removed most of the resin by repeatedly boiling out the wax with alcohol, allowing to cool and then separating the alcoholic resin-solutions; they then removed from the residue all that ether would dissolve. In the soluble part, after removing the last traces of resin by the charring action of thionyl chloride, they found a hydrocarbon which they believe to be normal dotriacontane $C_{32}H_{66}$, with m.p. 71°, and in the insoluble part they found an oxylactone $C_{30}H_{58}O_2$, with m.p. 88° to 88.5°, identical or isomeric with the lactone of lanoceric acid. They sum up the composition as 18 to 20 p.c. of resin, 74 to 76 p.c. of dotriacontane, and 5 to 6 p.c. of the oxylactone.

Berg (*Chem. Zeit.* 1914, 38, 1162) found: (a and b) about 50 p.c. of two hydrocarbons, one with m.p. 68° and the other with m.p. 84°–85°; (c and d) about 10 p.c. of a semi-fluid mixture of two cholesterols, these were free in the wax, when acetylated they yielded acetates, one a white powder, nearly insoluble in alcohol, the other readily soluble in alcohol on warming; (e) a small quantity of a substance containing oxygen, with m.p. 88°–89°, it was fairly soluble in alcohol, could be acetylated, did not give any cholesterol reaction, and must have been present in the wax as an ester; (f) a very small quantity of a substance containing oxygen, melting with decomposition at 243°, it was readily soluble in alcohol, from which it crystallised in leaflets, it could not be acetylated, it gave a colour reaction with acetic anhydride and sulphuric acid, and may be an ester of a lupeol-like cholesterol.

Buchner (*Chem. Zeit.* 1918, 42, 374) gives the composition as determined by Staempfli as: 50–52 p.c. of a hydrocarbon $C_{31}H_{64}$, with m.p. 68°; 25 p.c. of melissic acid $C_{31}H_{58}O_2$, present partly free and partly as a melissyl ester with m.p. 88°–90°; 10–14 p.c. of melissyl alcohol $C_{31}H_{64}O$, with m.p. 85° (whether free or as ester is not stated); 1 p.c. of another hydrocarbon, with m.p. 85°; traces of a phytosterol, with m.p. over 130°; and 10 p.c. of resinous matter; but none of the experimental evidence is given.

Uses.—Owing to its hardness it resembles carnauba wax. It is especially valuable in making shoe-dreams and polishes, as it imparts to such preparations the power of producing a brighter lustre than any other wax. On the other hand, when mixed with paraffin wax it

has not nearly as great a hardening effect as carnauba wax, and it has little hardening action when mixed with soft wax compositions. For candle making it is considered inferior to carnauba wax, owing to its lower melting-point (given as 65°), and for phonograph records its suitability is considered small. The insulation of telephone cables is another suggested use.

Cape berry wax. Samples of this wax have been shown at exhibitions in London, and it is capable of being collected in quantities in Cape Colony, but it has not yet come into any extensive use. It is probably derived from one of the species of *Myrica* growing in South Africa, which include *M. quercifolia* (Linn.), *M. cordifolia* (Linn.), and *M. serrata* (Lam.); it is similar to myrtle berry wax in its general characters and in its physical and chemical properties, which were found to be: sp.gr. 0.874 at 99°; m.p. 40.5°; m.p. of the fatty acids 47.5°; mean molecular weight of the fatty acids 236.1; acid value 4.1; saponification value 211.1; iodine value 1.1. It yields a hard white soap, but does not seem to be suitable for candle making (*Imp. Inst. Bull.* 1906, 4, 300). The results of another examination are: sp.gr. 0.9893; m.p. 49°; refractive index at 80° 1.4364; acid value 2.5; saponification value 212.3; iodine value 2.03; unsaponifiable matter 2.51 p.c.; fatty acids 89.7 p.c.; m.p. of mixed fatty acids 48.5°; solidifying-point of these 46.5°; mean molecular weight of these 241.4; it was described as South African berry wax, and was pale greenish-grey with a granular fracture; when melted it formed a greenish-brown muddy liquid, and it was filtered before examination (*Cooking, Chem. and Drug.* 1908, 73, 74).

Berry wax from *M. cordifolia* came into prominence during the war. The plant is grown as a sand-binder in the neighbourhood of Cape Town, Port Elizabeth, and other places. The wax was previously exported to Germany, and

was used for gramophones and for floor polish (J. Soc. Chem. Ind. 1918, 37, 74 R).

Carnaúba or carnaúba wax is derived from the carnaúba palm, *Copernicia cerifera* (Mart.) (*Corypha cerifera*, Linn.), which grows in Brazil, especially in the provinces of Ceara, Rio Grande do Norte, and Piahy. The trunk is 25-35 ft. high with a crown of leaves at the top. The young leaves of about 3 ft. long have a coating of wax on both the upper and under sides, which appears homogeneous to the naked eye. The wax layer is thicker on the upper side, and comes off in scales; on the lower side it is thinner and more adherent. The harvesting extends over the six dry months of the year, and the leaves are cut twice a month, about eight leaves being cut from a palm at a time, those leaves that have reached a certain stage of development being taken, leaving the very young leaves to develop later. If the leaves are allowed to become too old the wax is easily detached, and is lost before the leaves are brought to the ground. The leaves are spread out to dry, and are then slit up with a knife and beaten over a cloth to detach the wax which comes off in scales or as a greyish-white powder. A little water is added to the powder, and it is melted and poured into moulds, in which it solidifies in cakes of about 2 kilos. About 850 leaves give 16 kilos. of wax; about 1.8 kilos. of wax, valued at 1s. 6d., are obtained from one palm. On poor land 1200 leaves, and on good land only 500 leaves are required to give the 16 kilos. In some estimates, however, the yields are not so good as these.

The following table, based on Hambloch's Reports on Brazil, Dept. Overseas Trade, 1919, 1921, and 1922, shows the exportation of carnaúba wax:

Year	Metric tons	Value in £	Value per metric ton in £
1913	3867	439,500	114
1914	3315	324,200	98
1915	5897	505,100	86
1916	4166	398,900	96
1917	3669	443,300	121
1918	4215	1,135,200	269
1919	6200		
1920	3500		
1921	1540	January to June (inclusive)	
1922	2200	"	"

In 1913 Germany took 1710 metric tons; the United States 941; the United Kingdom 687; and France 509. In 1920 the United Kingdom took 1000 metric tons and the United States 2200.

Raw carnaúba wax is of a dirty yellowish or greenish colour, amorphous, hard, brittle, and easy to powder. In its outward appearance it is compact, but penetrated with very many air spaces; it is tasteless, and smells, when fresh, somewhat like fresh hay—i.e. of coumarin; later it becomes inodorous. It is purified by remelting, and has then a greenish-yellow or straw-yellow colour.

Analytical values.—The melting-point is variously given as from 80.5° to over 86°, it increases with the age of the sample, and an old specimen melted at 90°-91°; about 84° seems a common experience; light-coloured specimens have a somewhat lower melting-point than darker ones. The sp.gr. at 15° is 0.978-0.999.

The acid values recorded are from 0.3-10, about 4 being common; the saponification values from 69-88, and even 95; the iodine values from 5-14. In preparing bleached carnaúba wax additions, such as paraffin wax, are made so that the above values do not hold good for it. The wax is not easily saponified. Berg (Chem. Zeit. 1909, 33, 885) recommends the use of xylene as a solvent in order to hasten the saponification and to diminish the risk of oxidation occurring during long boiling with potassium hydroxide.

Composition.—Carnaúba wax is composed mainly of an ester of triacontyl, $C_{30}H_{61}$, with the acid $C_{27}H_{54}O_2$, which is either cerotic acid or an isomer of it. The triacontyl was formerly supposed to be the same as the melissyl of beeswax, but it now appears that melissyl is most probably $C_{31}H_{63}$. Carnaúba wax contains a considerable proportion of triacontyl alcohol $C_{30}H_{61}OH$. In addition there are a number of compounds present in small proportions.

Story Maskelyne (J. Chem. Soc. 1869, 87) found: (a) melissin (melissyl alcohol) both free and coming from an ester; (b) a compound with m.p. 105°, corresponding to $C_{30}H_{61}O_2$; (c) an alcohol with m.p. 78°, corresponding to $C_{32}H_{65}O$, and also other compounds.

Von Pieverling (Annalen, 1870, 183, 344) prepared from this wax melissyl alcohol and examined its products, he also obtained a small quantity of ceryl alcohol $C_{27}H_{54}O$.

A long investigation of the composition was made by Sturcke (Annalen, 1884, 223, 283), employing carnaúba wax with m.p. 83°-83.5°. He found that the principal component was the ester $C_{30}H_{61} \cdot C_{27}H_{54}O_2$, and that there was a considerable quantity of free wax alcohol present. When the wax is extracted with boiling alcohol a considerable proportion dissolves but separates again when the alcohol cools. He found when 1200 grms. of wax were boiled out with 5½ litres of alcohol and the hot clear solution was poured off that on cooling 350 grms. (equivalent to 29 p.c.) were deposited. By repeated extraction small quantities of the ester seem to be removed each time; thus when 10 grms. of the wax were boiled with half-litre lots of alcohol, 350 c.c. of the ninth lot contained 0.295 grm. and of the tenth lot 0.286 grm. By saponifying the wax and separating the products with petroleum ether, &c., and by many fractionations he found: (1) A hydrocarbon with m.p. 59°-59.5° present in small proportion. (2) An alcohol $C_{28}H_{57} \cdot CH_2OH$ with m.p. 76° in small proportion. (3) An alcohol

with m.p. 85.5°-85.7° in large proportion. From this he prepared the acid $C_{28}H_{57} \cdot COOH$ with m.p. 89.9°-90.2°. This alcohol he called myricyl (melissyl) alcohol, but according to Heiduschka and Gareis (J. pr. Chem. 1919, 99, 299) it contains CH_3 , less than the melissyl alcohol $C_{31}H_{63}O$ obtained from beeswax. (4) A dihydroxy alcohol $C_{28}H_{56}(OH)_2$, with m.p. 103.5°-103.8° in small proportion. From this he prepared the acid $C_{28}H_{56}(OOH)_2$, with m.p. 102.5°. (5) An acid $C_{28}H_{56} \cdot COOH$ with m.p. 72.5° in small proportion, isomeric with lignoceric acid. This acid was subsequently

called carnaubic acid by Darmstadter and Edschütz (Ber. 1896, 29, 620) in a paper on wool fat. (6) An acid $C_{22}H_{42}COOH$ with m.p. 78.8° – 79° , either identical or isomeric with the cerotic acid of beeswax, in large proportion. It would not crystallise when it solidified from the melted state, and for this reason he doubted its identity with the cerotic acid of beeswax.

(7) A lactone $C_{19}H_{38} \begin{smallmatrix} CH_2 \\ \diagup \quad \diagdown \\ CO \end{smallmatrix} O$ with m.p. 103.5° in small proportion. From this he prepared the acid $C_{19}H_{38}(COOH)$, with m.p. 89.5° – 90° .

It should be noted that these products were obtained after saponification. The hydrocarbon, no doubt, was free in the wax, and the $C_{19}H_{38}CH_2OH$ alcohol probably was partly free and partly came from the ester, but the others were not proved to be free before saponification. Besides these Stürcke also noticed, as had von Pieverling, a greenish balsam-like substance with an odour like coumarin, but in too small quantity for examination. Stürcke's results, it should be remarked, do not fully explain the analytical values given above, so further work on the composition is needed.

Liebermann (Ber. 1885, 18, 1979) obtained a substance from the wax by a great many fractional crystallisations with m.p. 92° , which could not be materially raised by further crystallisations; it formed a matted paper-like layer without any lustre; he did not, however, make an analysis of it.

Heiduschka and Gareis's work (J. pr. Chem. 1919, 99, 293) is described above under the composition of beeswax.

Bibliography.—Brande (Phil. Trans. 1811, 261), action of various solvents and reagents. Lewy (Ann. Chim. 1846, [3] 13, 449), percentage of carbon and hydrogen. Bérard (Bull. Soc. chim. 1868, 9, 41) found cerotic acid (a mistake probably) and an ester saponifiable by fusion with potassium hydroxide. Story Maskelyne (J. Chem. Soc. 1869, 22, 87), *see above*. Von Pieverling (Annalen, 1876, 183, 344), *see above*. Stürcke (*ibid.* 1884, 223, 283), *see above*. Valenta (Zeitsch. anal. Chem. 1884, 23, 257), melting-point of mixtures of this wax with commercial stearic acid, with mineral wax and with paraffin. Liebermann (Ber. 1885, 18, 1979), *see above*. A. and P. Buisine (Bull. Soc. chim. 1891, [3] 5, 654), effect of this wax as an adulterant of bees wax. Schaedler, Technologie der Fette und Öle, 2nd ed. 1892, 881. Gascard (J. Pharm. Chim. 1893, [5] 28, 49) prepared wax alcohols from beeswax, carnauba wax, and lac, and believed them to be melissyl alcohol in each case. The melting-point of those from carnauba wax and lac was 88° , and he purified that from beeswax and got its melting-point up to 88° by making its ester with melissic acid and then decomposing this. Villon (Bull. Soc. chim. 1893, [3] 9, 1046), collecting, bleaching, and uses. Brant, Fats and Oils, 2nd ed. 1896, ii. 144. Semler, Tropische Agrikultur, 2nd ed. 1897, i. 732. Chem. 1900, 39, 640), directions for finding the acid and saponification values, using amyl alcohol as solvent, thus facilitating saponification. Berg (Chem. Zeit. 1903, 27, 754), detection and analytical results. Badoliffe (J. Soc. Chem. Ind. 1906, 25, 158), analytical values, using amyl

alcohol as solvent. Engler (Chem. Zeit. 1906, 30, 711), the rotatory power. Berg (Chem. Zeit. 1909, 33, 885), xylene as solvent for finding analytical values. Leys (J. Pharm. Chim. 1912, [7] 5, 577), describes a new method of examining this wax and beeswax; he uses a mixture of amyl alcohol and fuming hydrochloric acid to dissolve the wax alcohols and separate them from the hydrocarbons; he found no hydrocarbons in carnauba wax. Lüdecke (Seifensieder Zeit. 1913, 40, 1237, 1274, 1302, 1327), descriptions of the commercial varieties, adulterants (fragments of candelilla wax are sometimes mixed in), detailed methods of finding melting-point, sp.gr., and analytical values. Buchner (Chem. Zeit. 1918, 42, 373) quotes Popp on the formula of melissic acid prepared from carnauba wax (Heiduschka and Gareis do not agree with Popp's formula). Heiduschka and Gareis (J. pr. Chem. 1919, 99, 293) compare melissyl alcohol from beeswax and its derivatives with the alcohol from carnauba wax and its derivatives and find them to differ by CH_2 .

Cochin China wax (*Cay Cay fat*, *Irvingia butter*). This is obtained from the fruit of the Cay Cay tree, *Irvingia Oliveri* (Pierre), a forest tree reaching the height of 100 ft., and growing widely in the east of Cochin China. The fruit is the size of a lemon, the endocarp has the size and shape of an almond with its outer covering, and the kernel, too, resembles in size and shape that of the almond. The fruits are ripe in July, and fall to the ground; they are gathered into heaps by the natives, and left for two months to allow the soft outer parts to decompose; they are then carried to the houses and dried in the sun. They are opened with a strong knife, and the kernels are removed, dried in the sun, and pounded in a mortar. The pulp is placed in a vessel having a bottom of plaited material; this is fixed above water in another vessel, and the water is heated, but not to boiling. When the pulp has become a sticky paste it is wrapped in a mat of rice straw, and submitted to pressure in a crude press, the operations being repeated several times, and the melted wax is either allowed to solidify in moulds or else is cast into candles in bamboo tubes. In the laboratory the dry kernels extracted with carbon disulphide gave 52 p.c. of wax. The wax is of a greyish-yellow colour, and is unctuous to the touch. The purified wax softens at 37° , melts at 38° , and solidifies at 34° (Vignoli, Le Cay Cay, Thèse présentée à l'École Supérieure de Pharmacie de Montpellier, 1886).

Bontoux (Les Matières Grasses, 1908, 1276; J. Soc. Chem. Ind. 1909, 28, 429) found that 100 dry seeds weighed 360 grms. and gave 78 p.c. of shells and 22 p.c. of kernels. The latter, on extraction with light petroleum, gave 60.45 p.c. of wax. The wax had the consistency and texture of beeswax, and was more brittle, with the same conchoidal fracture; its sp.gr. at 40° compared with water at 40° was 0.913; it melted at 39.7° in a capillary tube, and solidified at 31° ; its acid value was 0.86; saponification value 235.3; unsaponifiable matter 0.42 p.c.; iodine value 6.7; Reichert-Meissl value 0.62. The insoluble fatty acids, together with the unsaponifiable matter were 94.0 p.c., their m.p. was 38.8° ; solidifying point (titer test) 36.6° ; neutralisation value 250.2.

and mean molecular weight 224. Two samples of the wax of native origin had nearly the same values, but the acid values were 23.5 and 34.9, which, however, are not excessive, and they contained 0.16 p.c. and 0.19 p.c. of unsaponifiable matter. Bontoux prepared methyl esters, and concluded that the wax was mainly composed of myristin 60-65 p.c., laurin 30-35 p.c., and about 5 p.c. of olein. The wax gives a hard white soap. The production in Indo-China has declined, owing to the introduction of petroleum. A Cay Cay wax is also obtained from the fruit of the tree *Irvingia malayana* (Oliver), which grows in Cambodia. Other references are: Heckel, Annales de l'Institut colonial de Marseille, 1893; Apoth. Zeit. 1898, 169; Crevost, Les arbres à suif de l'Indochine, Hanoi, 1902; Bulletin économique de l'Indochine, Hanoi, 1902; Chem. Zeit. 1903, 27, 43.

Cow tree wax (Milk tree wax). In the north of Venezuela, in the neighbourhood of Caracas and of Lake Maracaibo, and in the valley of Canaguas, there grows a tree (*Brosimum Galactodendron*) called *Palo de vaca* or *Arbol de leche*, which yields a thick milk when incisions are made in its trunk; this is drunk like milk by the inhabitants. This milk, when heated, forms a skin, and if this is removed and evaporation continued, an oily liquid is obtained, together with a fibrous mass. The oily liquid when it has solidified, is a yellowish-white, hard translucent wax; it begins to melt at 40°, and is completely melted at 60°. It is insoluble in water, but is easily dissolved by essential oils. It dissolves in boiling alcohol and separates on cooling; it is saponifiable by caustic potash. It can be used like beeswax for making candles. Humboldt, Ann. Chim. 1817, 7, 182; Boussingault and Mariano de Rivero, *ibid.* 1823, 23, 219; Marchand, J. pr. Chem. 1840, [i.] 21, 43.

Esparto grass wax. In preparing the fibre of this grass for paper making the material reaches the mills in tightly compressed bales. It is there loosened by a special machine and at the same time freed from dust by a strong current of air from a powerful fan. This dust contains from 25-50 p.c. of wax, and in most mills is deposited in special dust collectors. The wax when obtained from the dust is hard, rather brittle, and of a light brown colour, and has the following characteristics: m.p. about 74°, loss of weight at 100° overnight about 1.5 p.c., ash 0.02 p.c., acid value 34.42, saponification value 71.41, iodine value 6.48, unsaponifiable matter (soluble in hot CCl_4) 50.34 p.c., fatty acids 45.69 p.c. The wax is in demand by some manufacturers and commands a good price; but unfortunately the quantity of dust obtainable at any one paper mill is not very large, so the output of wax is not equal to the demand (Budds, J. Soc. Chem. Ind. 1916, 35, 401).

Fig tree wax (Gondang or Kondang or Getah wax, Java or Sumatra wax). This wax is obtained in Java from the milky juice (*getah* in Malay) which runs from incisions made in the bark of the gondang, a wild fig tree (*Ficus variegata*, Blume. = *F. ceriflua*, Jungh. = *F. subracemosa*, Blume.). The juice is boiled with water until the wax separates. It forms a fairly hard cake, cream coloured within, turning brown in the air; it has a conchoidal fracture and can be powdered, but not readily. The

crude wax melts at about 80° to a very viscous mass, which, on cooling, remains viscous for a long time, and from which an aqueous liquid separates. The sp.gr. of the wax after melting is 1.015 at 15°. It softens at 55°, and is only completely melted at 73°. It is soluble in benzene, chloroform, carbon disulphide, oil of turpentine, light petroleum, and boiling ether. Boiling alcohol dissolves it slowly, and the greater part separates on cooling. Cold alcohol keeps in solution a little over 5 p.c. of the wax. By means of boiling alcohol over 70 p.c. of white crystalline purified wax can be obtained, melting at 61°, insoluble in cold alcohol, but soluble in boiling alcohol. Greshoff and Sack (Rec. trav. chim. 1901, 20, 68), by analyses and saponification of the wax thus purified, obtained results suggesting that it is an ester $\text{C}_{22}\text{H}_{44}\text{O}_2$ of an alcohol $\text{C}_{17}\text{H}_{34}\text{O}$ (flococeryl alcohol), with m.p. 198°, and of an acid $\text{C}_{12}\text{H}_{24}\text{O}_2$ (flococeric acid), with a m.p. 57°, this ester is probably associated with some accessory substance; they also think the original wax contains some free flococeryl alcohol.

Vogl (Lotos, published at Prag, 1872, 22, 54) describes Sumatra wax or Getah Lahoe coming from the same tree. Kessel (Ber. 1878, 11, 2112) assigns formulae to components of the wax which differ from the above. Ultée (Chem. Zeit. 1915, ii. 794, from Pharm. Weekblad. 1915, 52, 1097) examined the milky sap of *Ficus variegata*; it contained 35 p.c. of solids, and when coagulated by heating, or by alcohol, or by dilute acetic acid it yielded gondang wax. From this by suitable treatment, including a saponification, he obtained a wax alcohol, the flococeryl alcohol of Greshoff and Sack. This alcohol he identified as being the same as β -amyryn with m.p. 197.5°. (β -amyryn is $\text{C}_{20}\text{H}_{40}\text{O}$ and comes from elemi resin.) In the wax itself he found lupeol acetate with m.p. 190°-197°, but no free β -amyryn.

Insect wax. This is also called *Chinese wax*, *Chinese tree wax*, *Vegetable spermaceti*, and sometimes, but incorrectly, *Japanese wax*; it must not be confused with Japan wax. It is the secretion of an insect *Coccus pala* (Westwood), *Coccus confusus* (Fabr.). The industry of its production is peculiar, in that the insects are bred for the purpose of producing eggs in one district, and these eggs are then transported to another district where the insects are reared to produce wax. The Chien-Chang valley in the prefecture of Nung Yuan Fu (Long. 102° 26', Lat. 27° 54') in the Sze Chuan province of China is the great breeding-ground of the wax insect; it is about 5000 ft. above sea-level. Here the insects are reared on the *Ligustrum lucidum* (Ait.) or large-leaved privet. In March, when the trees were seen by Mr. Hosie, he found numerous brown pea-shaped excrescences attached to the bark of the boughs and twigs. The larger of these were readily detachable, and when opened presented either a whitish-brown pulpy mass or a crowd of minute animals like flour, whose movements were just perceptible to the naked eye. From 2 to 3 months later these had developed in each case into a swarm of brown creatures, each provided with six legs and a pair of antennae; each of these was a wax insect. Two hundred miles to the north-east of the Chien-Chang valley, and separated from it

series of mountain ranges, is the prefecture of Kia-ting-fu (Long. 104° , Lat. $29^{\circ} 34'$), also called Chia-ting-fu, containing the district of Omi and the valley of the Ya river, the headquarters of the wax-producing industry. The scales produced in the Chien-Chang valley are ready for removal by the end of April, and are then full of eggs; they are made up into paper packets, each weighing about 16 oz. Sixty of these packets make a load, and are conveyed by coolies from the Chien-Chang valley to the town of Hung Ya in the Kia-ting-fu prefecture for sale to the farmers. In May thousands of coolies are engaged in the traffic. They travel only at night, in order to avoid the high temperature of the day, which would tend to the rapid development of the insects and their escape from the scales. At the stopping places the packets are opened out in cool places; but in spite of this, each packet is found to have lost on an average an ounce in transit. A pound of scales laid down in Kia-ting-fu, in years of plenty, costs about half a crown; in bad years the price is doubled. In favourable years a pound of scales will produce 4-5 lbs. of wax. In the plain around Kia-ting-fu the plots of ground are thickly edged with stumps of *Frazinus chinensis* (Roxb.), a species of ash varying from 3 or 4 to 12 ft. high, with numerous sprouts rising from their gnarled heads, and resembling at a distance pollard willows. On the arrival of the scales they are made up into small packets enclosed in a leaf of the wood-oil tree. The edges of the leaf are tied together with a rice straw, by which the packet is suspended close under the branches of this ash. A few rough holes are drilled in the leaf with a blunt needle, so that the insects may find their way through to the branches. On emerging from the scales the insects creep rapidly up to the leaves, among which they remain for a period of 13 days. They then descend to the branches, on the underside of which they take up their position, and commence to deposit the wax. This first appears as an under-coating on the sides of the boughs and twigs, and resembles quinine sulphate or a covering of snow. It gradually spreads over the whole branch, and attains, after 3 months, a thickness of about a quarter of an inch. After the lapse of 100 days the deposit is complete, the branches are lopped off, and as much of the wax as possible is removed by hand. This is placed in an iron pot of boiling water, and the wax on rising to the surface is skimmed off and placed in a round mould, whence it emerges as the insect wax of commerce. Where it is found impossible to remove the wax by hand, the twigs and branches are thrown into the pot, so that this wax is darker and inferior. The insects which have sunk to the bottom of the pot are placed in a bag and squeezed of the last drop of wax, and are then thrown to the pigs. Not only the *Frazinus chinensis*, but also the *Liquidum lucidum* is used in the final wax-producing stage of the industry. The wax is used for coating the exterior of animal and vegetable tallow candles, as it serves to hold in the more fusible tallow when the candle is burning; a little is also mixed with the tallow; it is employed to give a gloss to paper, for coating glass, and a polish for furniture and ieda-ware.

(Nature, 1891, 43, 291; Wilson, Chemist and Druggist, 1906, 68, 143; Bull. Imp. Instit. 1924, 22, 64; Pharm. J. 1924, 27, 278).

Insect wax is white and crystalline, resembling spermaceti in appearance, but it is harder and more fibrous; it is brittle, and at 15° can be powdered. Its sp.gr. is 0.970 at 15° (0.926 at 15° , Gehe and Co., Zeitsch. anal. Chem. 1895, 34, 765) and 0.809-0.811 at 98° - 99° ; m.p. 80° - 83° ; saponification value 80-93; iodine value 1.4. It is only very slightly soluble in alcohol and ether, but is readily soluble in naphtha, from which it can be crystallised. Brodie (Phil. Trans. 1848, 159) saponified the wax by melting it with potash, and obtained an alcohol and an acid; the alcohol he named *cerotin*, and to it he assigned the formula $C_{17}H_{34}O$, it is now called *ceryl alcohol*; the acid he considered to be the same as the cerotic acid he had obtained from beeswax, to which he had assigned the formula $C_{27}H_{54}O_2$; the wax he regarded as ceryl cerotate, the ester of this alcohol and acid. Brodie's formulae have been supported by Gascard (*see below*). Marie (J. Chem. Soc. 1897, 72, 1, 318) proposes $C_{26}H_{52}O_2$ or $C_{25}H_{50}O_2$ for the cerotic acid of beeswax; and Henriques (*ibid.* 460) regards ceryl alcohol and cerotic acid from insect wax as $C_{26}H_{52}O$ and $C_{26}H_{52}O_2$, and it is stated that the identity of the cerotic acids from insect wax and from beeswax is not quite certain. Other substances besides ceryl cerotate are probably present.

Gascard (Compt. rend. 1920, 170, 1326) investigated the formulae for the ceryl alcohol and for the cerotic acid obtained from insect wax, and confirmed those of Brodie, namely, $C_{17}H_{34}O$ with m.p. 80° for the alcohol and $C_{27}H_{54}O_2$ with m.p. 82° - 82.5° for the acid; but thought that the acid must be different from the cerotic acid of beeswax that Marie prepared with m.p. 77.5° . The following was his method. He started with insect wax with m.p. 80.5° - 81° , and first purified the ester, ceryl cerotate, by extraction with boiling acetone; the undissolved ester after recrystallisations from benzene melted at 84° . He saponified this by boiling with alcoholic potassium hydroxide. He then added calcium chloride and obtained a precipitate of calcium cerotate; from the filtrate he obtained the ceryl alcohol which, after purification, melted at 79° - 80° . From this he prepared the iodide and found that the percentage of iodine in it corresponded to $C_{17}H_{33}I$. From the iodide he obtained the hydrocarbon which melted at 59.5° ; thus agreeing with Kraft's $C_{17}H_{34}$. As regards the acid, he obtained it from the calcium cerotate and found that it melted at 82° - 82.5° . He also prepared some from the ceryl alcohol by oxidation with potassium bichromate in acetic acid solution; after purification it melted at 81.5° - 82° , and by titration he found that its molecular weight corresponded to $C_{27}H_{54}O_2$. By further purification it melted at 82° - 82.5° , like the acid got by saponification.

Japan wax (Japan tallow, *Banach masu*, Vegetable wax of Japan). This must not be confused with insect wax which has sometimes been called Japanese wax. Japan wax is one of the most important of the vegetable waxes, large quantities being exported from Japan. Before 1854, whilst Japan was closed to foreigners,

except to the Dutch, it came through China and Singapore, and was imported in small quantities coming in small thin cakes, but after the opening of certain Japanese ports to British merchants, it arrived in large quantities and in square blocks or cases of about a picul each (133½ lbs.).

It is derived from the berries of three species of *Rhus* that grow in Japan, namely, *R. succedanea*, L., *R. vernicifera*, De C., and *R. sylvestris*, S. and Z. *R. succedanea* grows in the southern parts of Japan and yields wax only, but *R. vernicifera*, which has a more northerly range, yields a more important product, namely, the well-known Japanese lacquer, which is prepared from its sap, but its berries are also used as a source of wax. *R. sylvestris* is a less important source. *R. succedanea* and *R. vernicifera* also grow in China. The berries of all three are composed of an outer skin, a mesocarp in which is the wax, and a kernel.

In Japan to obtain the wax the berries are reduced to a meal—some authors say that they are previously slightly roasted; the meal is heated by steam in hempen sacks and then quickly squeezed in a wedge press to force out the wax. The residue is again treated in the same way. In the case of *R. vernicifera* the kernel is easily separated and is removed in the course of crushing, but in the case of *R. succedanea* the wax adheres to the kernel in spots, and it is not clear from the accounts of the process whether the kernel is separated or crushed with the mesocarp. The methods, no doubt, vary in different localities. It has been stated that perilla oil is added to obtain the last portions of the wax, but this is denied by Tsujimoto (Lewkowitsch and Warburton, Oils, Fats, and Waxes, 6th ed. vol. ii. 1922, p. 45), who states that a proportion of the kernel oil of *R. succedanea* is added. With respect to this oil, A. Meyer (Arch. Pharm. 1879, [3] 15, 119, 120) found in the cotyledons contained in the kernels of *R. succedanea*, after carefully removing the shells, 36 p.c. (30 p.c. ?) of fat, or 2.65 p.c. on the whole fruit. It was yellowish-green, melted at 30°, was not a drying oil, and dissolved in about 30 parts of alcohol at 30°. Crowe (Consular Rep. for Japan for 1912, p. 43) says that by the use of benzene an additional 10 p.c. of wax can be obtained, and that several works were adopting the system.

The yield is from 15 to 25 p.c. Impurities are removed by melting and skimming off the clear wax. It is bleached by melting it and allowing it to drop through woollen bags into cold water, so as to subdivide it into small pieces. These are exposed to the sun and are sprinkled with water and frequently turned over; the process occupies about 30 days.

The wax is pale yellow and hard with an even or conchoidal fracture; it becomes yellowish brown on keeping, and acquires a white waxy surface. The m.p. varies from 48° to 56°, that usually found being 53°; the wax solidifies again at about 41°, and when recently solidified melts at 42°; it slowly regains the higher melting-point. It is said that on warming it becomes transparent 10°–12° below its melting-point (Schaeffler).

Its specific gravity is close to that of water, and as it contracts and expands at a greater

rate than water, it exhibits the peculiar property of sinking, hovering or floating in water at different temperatures, sinking in cold water and floating in water somewhat warmer. After melting and resolidifying its specific gravity is lowered, it rises again in the course of some months. Thus a sample which hovered at 16.2° was melted and resolidified, it then hovered at 8.0°. Remembering that its expansion is greater than that of water, its specific gravity at 16.2° would be materially less than it was before melting, and it would float in water of that temperature. There is some variation in the specific gravity of different samples.

It is readily soluble in benzene and petroleum-ether and sparingly soluble in cold ether; it is insoluble in cold alcohol, but dissolves on warming and separates again on cooling.

In and after 1900 the following analytical values have been recorded: Acid value, 11.2–32.6; it is very variable, but values between 14 and 20 seem most common. Saponification value, 206.6–237.5; values between 215 and 224 being common. Iodine value, 8.3–15.1. Hubl, in 1884, records the iodine value as 4.2, so it is thought that the method of obtaining the wax has been changed. Part of the iodine value has been ascribed to the use of perilla oil mentioned above, as this oil has a very high iodine value. Ahrens and Hett in some wax prepared from berries obtained from Japan found iodine values of 11.9–12.8, and after bleaching in the sun, of 7.6.

Composition.—Japan wax is chiefly composed of glyceryl palmitate together with some free palmitic acid. Besides these a good many other substances have been obtained from it in small proportions; they may have been free in the wax or may have come from esters. These substances are: (1) About 1 p.c. of janic acid $C_{21}H_{42}O_4$ with m.p. 117°–117.9°; it is normal nonadecamethylene dicarboxylic acid $CO_2H\cdot(CH_2)_{19}\cdot CO_2H$. There is some evidence that the janic acid comes from a mixed ester of glycerol with janic acid and palmitic acid existing in the wax. (2) and (3) Smaller proportions of the two next lower acids, namely,

(4) Five to six per cent. of acids soluble in water, perhaps including suberic acid and isobutyric acid. (5) An odour of cenanthyl aldehyde is given off during saponification. This may be due to the oxidising action of bleaching agents, products being formed from which potassium hydroxide liberates cenanthyl aldehyde. (6) Pelargonic acid. (7) An acid with m.p. 87° and formula $C_{17}H_{34}O_2$ or $C_{18}H_{36}O_2$. (8) and (9) Very small quantities of liquid acids, one insoluble in water and one soluble. (10) and (11) Very small quantities of oleic and stearic acids, perhaps due to some addition made in the course of the manufacture of the wax.

The unsaponifiable matter resembles ointment in appearance, and is recorded as from 0.54 p.c. to 1.63 p.c.; in it have been found: (12) Melissyl alcohol with m.p. 88°. (13) Ceryl alcohol with m.p. 79°. (14) A saturated alcohol with m.p. 65° and with formula $C_{11}H_{22}O$. (15) A phytosterol with a double binding and m.p. 130°; as air-dried it is $C_{27}H_{44}O_2$, the specific

rotatory power is -22.11° , nearly the same as that of the phytosterol of cotton-seed oil. (16) About 60 p.c. of the unsaponifiable matter is a mixture of liquids, unsaturated and containing oxygen.

Uses.—It is only the bleached wax that is exported. It is said to be used for floor, furniture, and boot polishes and in laundry work; but there appears to be some secrecy about its exact use. Added to beeswax it imparts more solidity to the candles and causes them to leave the mould more easily; it is used instead of beeswax for a similar purpose in some rubber factories. Before 1859 the wax or the free acids obtained from it was used for candles and night-lights (Wilson, J. Soc. Arts. 1858-59, 7, 424). Lewkowitsch and Warburton (Chem. Tech. of Oils, Fats and Waxes, 6th ed. vol. ii. 1922, p. 667), however, says that the difficulties of employing Japan wax fatty acids for candles have not yet been overcome. It emulsifies well with water and has been used for currying leather (J. Soc. Chem. Ind. 1898, 17, 167). In Japan it is used for polishing turned wood and cabinet work; unbleached it is used for the candles of the jinriksha men and (unbleached?) in a composition for keeping the women's hair glossy and straight.

Bibliography.—Japan wax, like other substances which are of pharmaceutical interest, has a long bibliography. Kaempfer (Amoenitates Exoticæ, 1712, pp. 791, 794); Thunberg (Flora Japonica, 1784, p. 121); Siebold (Voyage au Japon, 1823-30, published 1838, i. p. 276). These three authors were surgeons in Dutch employ, and thus were enabled to visit Japan when it was closed to other Europeans; they mention the wax and the trees from which it was obtained. Oppermann (Ann. Chim. 1832, 49, 240), percentage composition. Landerer, H. Müller and Buchner (Repert. f. d. Pharm. 1833, 44, 1-34), discussion and experiments as to whether Japan wax is identical with adipocere from dead animals, and whether it is a North American product. Nees von Esenbeck (*ibid.* 1833, 46, 283), commenting on Landerer's work, says that he has seen wax from *R. succedanea* from Japan, and that it is quite the same as that found in commerce. Trommsdorff (J. pr. Chem. 1834, 1, 151), properties and trial as a candle. Brandes (Arch. Pharm. 1841, [2] 27, 288), composition. He thought that Japan wax was composed of the supposed compound ceric acid that Hess (Pogg. Ann. Phys. Chem. 1838, 43, 382) obtained by the treatment of rye-starch with nitric acid. Sthamer and Meyer (Annalen, 1842, 43, 335), composition, distillation, and oxidation by nitric acid. They found that Japan wax is glyceryl palmitate. Hanbury (Pharm. J. 1852-53, [1] 12, 476, and Hanbury's Science Papers, 1876, 60), description and melting-point. Berthelot (Ann. Chim. 1854, [3] 41, 242) suggested that Japan wax perhaps contains a dipalmitin. Simmonds (J. Soc. Arts. 1858-59, 7, 611) and Wilson (*ibid.* p. 424), source and use for candles and night-lights. The Pharm. J. 1859-60, [2] 1, 176), the J. Pharm. Chim. 1859, [3] 85, 368), and the Neues Repert. f. Pharm. (1860, 9, 74) give summaries from various authors. Jackson and Rogers (Proc. Boston Soc. Nat. Hist. 1859-61, 7, 54, 58), properties. Kopp (Rep. Chim. Appliquée, 1860,

2, 142 and 296), discussion of Jackson and Rogers' work; the melting-points were incorrectly reported on p. 142. Blockrode (*ibid.* p. 388), particulars some incorrect, also questioning the identity of the wax examined by previous authors. Simon (Bull. Soc. Imp. Zoo. D'Acclimation, 1862, 9, 596). He was an agent of the Ministre de l'Agriculture and wrote from Nagasaki, giving particulars of the exploitation per 10,000 trees of *R. succedanea* occupying 2 hectares and of the preparation of the wax. Roucher (J. Pharm. Chim. 1872, [4] 16, 20), peculiarities of the melting-point and use in pharmacy for making cerates with olive oil. Ludwig (Arch. Pharm. 1872, [3] 1, 213), particulars. Robertson (Consular Report on Trade of Kanagawa in Japan, 1874, 64; also in J. Soc. Arts. 1873-74, 22, 787; also in Pharm. J. 1874-75, [3] 5, 584), source and preparation. Further particulars about source, preparation and use (J. Soc. Arts. 1873-74, 22, 1000; also in Pharm. J. 1874-75, [3] 5, 425). *Naturalising R. succedanea* in France (Pharm. J. *ibid.* p. 448). Mexican myrica wax (*Mexican myrtle wax*)

This wax is obtained by the Indians in Mexico from the fruit of *Myrica jalapensis*, and is sold in Mexico city, where it is used for making candles. The tree is known locally as 'arbo de la cera,' and occurs in Vera Cruz, sometimes in dense thickets covering considerable areas. The wax forms a greenish-white layer on the outer surface of the fruit, and is obtained by boiling the fruit in water and skimming off the floating melted wax; it is refined by melting and straining. On examination it gave the following values, which resemble those of Cape berry wax: sp.gr. 0.8763 at 99°; m.p. 43.2°; acid value 4.07; saponification value 214.5; iodine value 2.38. It is considered that it would be suitable for making candles and soap (Olsson-Seffer, Bull. Imp. Inst. 1909, 7, 410).

Myrtle berry wax (*Myrtle wax*, *Laurel wax*, *Bayberry tallow*) is obtained from the wax myrtle, *Myrica cerifera* (Linn.), a shrub growing on peaty soil in North America, and common along the North Atlantic sea coast. The fruit is brown or blackish and the size of a pea; it secretes the wax and becomes covered with a snow-white crust, penetrated by brown or black points of the skin, so that the wax can only be got off as a powder and not in coherent pieces.

Wax is also got from other Myricaceae, namely, *M. caracasana* (Humb. and Bonpl.) in South America, especially in Columbia and Venezuela, and *M. aethiopica* (Linn.) in Abyssinia. See also *Cape berry wax* and *Mexican myrica wax* above.

To obtain the wax the berries are boiled with water, and the fatty mass that floats on the surface is skimmed off and poured into flat dishes; the yield of wax is from 20 to 25 p.c., and a bush yields from 10 to 15 kilos. of berries. The wax which comes from the United States has a deep green colour, probably due to chlorophyll; this colour is bleached to a grey-yellowish tint by exposure to light and air for several years, but the change extends only a few millimetres below the surface.

The statements as to its composition are not concordant. Smith and Wade (J. Amer. Chem. Soc. 1903, 25, 629), however, examined the wax, preparing it by extracting the berries with light petroleum, and concluded that it was mainly palmitin (glyceryl tripalmitate) with some lower glyceride and a small amount of

free acid; they obtained pure palmitin by crystallising four times from light petroleum. The berries they used were picked in September, and the extraction and examination were made in November. The values they record are: sp.gr. 0.9806 at 22°/15.5°, and 0.879 at 99°/15.5°; refractive index at 80° 1.4363; acid value 30.7; saponification value 217; iodine value (Hübl) 3.9; Reichert-Meissl number 0.5. From these they inferred the absence of oleic and volatile acids. They also concluded that no stearin was present. The m.p. in this sample was 48°, as determined by Allen's method (Coml. Organ. Anal. 3rd. ed. vol. ii. pt. i. 34), and the solidifying point was 45°; but it was found that the melting-point rises considerably on keeping the wax. A redetermination in March of the m.p. gave it as 52.5°, a rise of 4.5° in 4 months. A specimen of wax about 4 years old melted at 57° and solidified at 58.3°. Wax from berries obtained in August and extracted in March melted at 55.4°.

Some other observers have found the acid value to be only about 4. It is inferior to beeswax in ductility and plasticity; mixed with beeswax it can be employed for making candles; these are said to give a pleasant smell when extinguished. It could probably be used for soap making. Chittenden and Smith (Amer. Chem. J. 1884, 6, 217) employed this wax as a source for preparing pure palmitic acid.

Some wax prepared in Colombia from the berries of *M. arguta* was examined at the Imperial Institute (Bull. Imp. Inst. 1918, 16, 287) with the following results: m.p. 45°; solidifying point of the fatty acids 46.4°; acid value 21.2; saponification value 216.7; iodine value 1.03; unsaponifiable matter 0.4 p.c.; the wax was yellowish-buff in colour and had a peculiar odour, similar to that of myrtle wax from South Africa (Cape berry wax). It was stated that the wax is employed in Colombia for the manufacture of soap and candles, that the plant is abundant, that the fruit can be gathered cheaply and easily, and that the extraction of the wax is not difficult.

Ocuba wax is obtained from the fruit of a shrub growing in the Pará province of Brasil. It grows well in marshy places, and is found in abundance along the banks of the Amazon river. The fruit encloses a nut covered with a thick skin. The skin extracted by water gives a fine red colour (Ocuba red); after washing with water the nuts are thrown in heaps, crushed to a paste, and boiled, when the wax separates and floats on the surface. The crude wax resembles beeswax, and by purification can be obtained white and suitable for candle-making. 100 kilos. of the seeds give 20-22 kilos of wax. The product is said to be a mixture of wax, fat, and resin, to melt at 40°, and to have a sp.gr. of 0.920 at 15°; it is only slightly soluble in cold alcohol, but is completely soluble in boiling alcohol and ether (Chem. Revue über die Fett- und Harz-Industrie, 1901, 8, 213). See also *Ucububa wax*.

Palm tree wax is the product of a palm tree *Ceroxylon andicola* (Humb. and Bonpl.), which grows on the Andes in Colombia at altitudes of 7900-9700 ft.; it attains a height of 100 ft., and the trunk is coated with the wax, which gives it a white and marble-like appearance.

The wax is obtained by cutting down the tree and scraping off the coating, which is then boiled with water; the wax is thus softened and floats on the surface, and impurities are removed. One tree is said to yield 25 lbs. The wax is made into balls and dried in the sun. Candles are made from it by the addition of a little tallow, and are sold in Carthago. That which is obtained from the Indians is yellowish-white, porous, and friable. When melted it is dark yellow, slightly translucent and fragile like resin. It is partly wax and partly resin, and melts at a temperature a little above that of boiling water; it becomes strongly electric by friction. It is readily soluble in hot alcohol; on cooling the solution becomes a white congealed mass. By using large quantities of alcohol and allowing the solution to cool the waxy part separates and the more soluble resin remains in solution; by repeating this operation several times the wax can be separated from the resin and from a small amount of a bitter substance. Ether also dissolves it, and by evaporation feathery crystals can be obtained. The purified wax melts below the temperature of boiling water, and then resembles beeswax, whilst the resinous matter melts above this temperature (Boussingault, Ann. Chim. 1825, 29, 330; 1835, 59, 19; Seemann, Pop. Hist. of the Palms, 1856, 222).

Bonastre (J. Pharm. Chim. 1828, 14, 349) obtained purified wax by repeated extractions with cold alcohol, and then dissolving the residue in boiling alcohol and filtering. When cold the solution became thick and opaque, like an aqueous starch solution; on standing for some months crystals appeared. On removing the alcohol white silky crystals were obtained; when dried and ground in a mortar it gave luminous sparks. He named this purified wax *cerosylène*, or, according to Boussingault (l.c. 1835, 59, 21), *cérosilène*. Lewy (Ann. Chim. 1845, [iii] 13, 447) found that the wax purified from the resin melted at 72°, and contained carbon 80.73 p.c., and hydrogen 13.30 p.c. Teschemacher (Mem. and Proc. Chem. Soc. 1845, 25) also describes this wax.

A wax obtained from the leaves of *Ceraxylon andicola* was examined at the Imperial Institute. It was a pale straw-coloured powder. After purification it gave the following analytical values: m.p. 93° by the open tube method, as compared with 84° for carnaúba wax, and 70–72° for candelilla wax by the same method; sp.gr. at 15°/15° 1.018; acid value 19.8; saponification value 73.7–104.4, varying with the conditions of the experiment; iodine value 32.8. It was thought that when purified it might be used as a substitute for carnaúba wax (Imp. Inst. Bull. 1917, 15, 182, and 1919, 17, 249).

Peat wax. Waxy substances are obtained when peat is extracted with suitable solvents. By means of benzene or toluene from 1 to 8 parts of crude wax have been obtained from 100 parts of the dry material of samples from different sources. This crude wax was found to contain sulphur, usually amounting to less than 1 p.c. of the wax, but in one case reaching 2.2 p.c. The crude wax consisted of some resinous matter, but principally of a mixture of ester and free acid. The acid or acids obtained by the saponification of the crude wax corresponded in composition to a fatty acid containing

about 22 carbon atoms; the alcohol thus obtained appeared to contain about the same number. No trace of glycerides was found (Kraemer and Spilker, Ber. 1902, 35, 1212). A process was patented in 1903 by Bouchaud-Praceiq (Fr. Pat. 338736) for extracting peat, lignite, &c., with alcohol or ethyl ester, &c., and recovering the wax from the solvent. The wax is said to be hard and to resemble beeswax, and to have a higher melting-point and a sp.gr. above 1.000 (J. Soc. Chem. Ind. 1904, 23, 710).

Zaloziecki and Hausmann (Zeitsch. angew. Chem. 1907, 20, 1141), by extracting peat with alcohol, obtained a dark yellow or brown waxy substance, but the yield was only 10 grms. from some kilograms. It had no sharp melting-point, melting between 80° and 96°; it dissolved very easily in amyl alcohol, and less readily in ethyl and methyl alcohols. In ethyl ether or benzene it dissolved only partially, giving a dark green liquid and leaving a brown insoluble residue. By saponifying the substance soluble in ethyl ether an alcohol was obtained, melting between 124° and 130°, and having a composition and molecular weight corresponding to $C_{20}H_{40}O_4$, and also an acid which began to soften at 145° and melted at 184°, having a composition and molecular weight corresponding to $C_{18}H_{36}O_2$. The part insoluble in ether gave on saponification an alcohol having the same melting-point, composition and molecular weight as the other alcohol, but differing a little in its behaviour, and also an acid which had not melted when 260° was reached, and which had a composition and molecular weight corresponding to $C_{31}H_{62}O_7$. Small quantities of other substances appeared also to be present in the wax, and the above substances are very possibly mixtures.

Pisang wax. This wax occurs as an excretion on the leaves of a species of *Musa*, which grows wild in Java, especially in the uncultivated regions of Tjilatjap and Koenigan. *Pisang* is the Malay name for the banana. The natives obtain the wax by scraping the leaves, throwing the scrapings into boiling water, and then collecting the melted wax. It is said that one stem bears on the average seven leaves (a leaf may be as much as 6 ft. in length), and that 100 leaves yield $\frac{1}{2}$ kilo. of wax. The cakes of wax are white, cream, or slightly greenish in colour, and slightly transparent; the wax is hard with a coarsely granular or crystalline fracture and is very friable. It has been examined by Greshoff and Sack (Ber. trav. chim. 1901, 20, 65), who record the following: sp.gr. 0.963–0.970 at 15°; m.p. 79°–81°; acid value 2–3; it is very hard to saponify, and the saponification value found was 109. Boiling alcohol dissolves very little (about 1 p.c.), and on cooling only retains 0.2 p.c. It is easily soluble in boiling oil of turpentine, amyl alcohol, or carbon disulphide. At 15° petroleum, ether, acetone, and oil of turpentine retain 1 p.c. or less; chloroform and carbon disulphide retain less than 2 p.c. On the basis of ultimate analyses of the wax (previously freed from the part soluble in boiling alcohol), and of the acid and alcohol obtained by saponification, the authors propose provisionally the three following formulae: $C_{21}H_{42}O_4$ for the wax, regarding it as an ester formed from $C_{20}H_{40}O_4$

stearic acid, and $C_{18}H_{36}O$ *pisinoceryl alcohol*. The acid melts at 71° and the alcohol at 78° .

Raphia wax. The raphia palm, *Raphia pedunculata* (Beauv.) or *Ruffia*, which grows in Madagascar, furnishes the fibrous material used by gardeners and known as 'bass'; this is the epidermis of the upper side of the palm leaf. The dull under surface is coated with a whitish layer or bloom, which can be easily rubbed off. After the bass is removed large quantities of the residues are available as a source of the wax. They are spread out to dry on cloths in the open air, but must be sheltered from the wind as the light waxy matter is easily blown away. After drying for 2-4 days a white coating is apparent on the under surfaces of the leaves; this is detached as a powder by shaking or rubbing the leaves between the hands. The powder is collected, freed from foreign matter by sifting, and then put into boiling water when the wax melts and floats on the surface, and earthy impurities settle to the bottom. The melted wax is separated and allowed to solidify. It is yellow to dark brown in colour, and rather harder and more brittle than beeswax. In an experimental trial it was found that ten leaves of medium size ($3\frac{1}{2}$ - $4\frac{1}{2}$ metres in length) weighed 104.5 kilos, and yielded 0.75 p.c. of wax; the yield in practice, however, would be less than this.

Raphia wax in its physical properties resembles carnauba wax but differs chemically; it seems likely to be applicable to the manufacture of candles, polishes, &c., if it can be produced at a sufficiently low cost.

Two specimens were found to have the following properties: m.p. 82° , 83° ; sp.gr. 0.836, 0.832 at $99^{\circ}/15.5^{\circ}$; acid value 4.9, 6.5; saponification value 51.3, 50.3; iodine value 7.7, 10.7 (Bull. Imp. Inst. 1908, 6, 380). It is only slightly soluble in alcohol, ether, acetone, chloroform, light petroleum, and carbon disulphide. It dissolves, but not completely, in boiling alcohol, and separates on cooling. It appears to be mostly composed of an alcohol or mixture of alcohols having a composition corresponding to $C_{22}H_{44}O$, but differing from arachic alcohol (Compt. rend. 1905, 141, 1251; 1907, 144, 594).

In 1918 the raphia wax industry was stated to be still undeveloped, but it was believed that 10 tons would be available annually (J. Soc. Chem. Ind. 1918, 37, 240 R, from U.S. Com. Rep. Apr. 1, 1918).

Rhimba wax. In the Chamber of Commerce Journal, 1901, p. 192, an account taken from the *Moniteur Officiel du Commerce* is given of a product furnished by the Rhimba tree of Madagascar. From the description it appears to be composed of both wax and resin. The wax is said to amount to 14 p.c. The particulars about it are not clearly stated. The wax is said to resist attempts to bleach it.

Snow brush wax. The snow brush (*Ceanothus velutinus*, Douglas) is a shrub from two to six feet in height, which grows in Californian forests; it is considered a nuisance and to involve fire dangers. Scollions and Blakemore made an investigation to see if it could be utilized. Besides obtaining tannin they found that the dried leaves yielded 7.3 p.c. of wax when extracted with gasoline. The wax was greenish in colour,

owing to the presence of a little chlorophyll, and when freed from solvent was brittle with a conchoidal fracture. The crude wax gave the following analytical results: free acid 20.3; saponification number 93.4; iodine value 19.5; Reichert-Meissl number 7.5; sp.gr. at 15° 0.988; melting point 78° - 79° . From experiments made to ascertain the components of the wax, they inferred that it was probably composed in great part of ceryl and melissyl esters of palmitic and stearic acids together with hydrocarbons, free cerotic acid and a small quantity of glycerides (J. Ind. Eng. Chem. 1916, 8, 411, 573).

Spermaceti occurs in special cavities in the head of the sperm whale or cachalot, *Physeter macrocephalus* (Linn.), and also in the blubber; it is held in solution by the sperm oil at the temperature of the whale's body. It also occurs in the bottle-nose whale *Balaena rostrata*, and in some other cetaceans, but not in the oil of the whalebone whales. The spermaceti from *Balaena rostrata* has a slightly higher melting point than that from the sperm whale. The great bulk of the head of the sperm whale consists of dense cellular tissue infiltrated with spermaceti, this is surmounted by the 'case' which holds nearly a ton of very fine oil and spermaceti known as 'head matter.' When removed this head matter is full of spermaceti crystals. The blubber surrounds the whole body in a layer about 18 ins. thick; it is 'tried down,' that is heated to separate the oil from the tissue; on cooling the oil deposits thick scales of spermaceti and becomes semi-solid. The 'trying down' is sometimes done on the ship and sometimes at the factories. At the latter the semi-solid mass undergoes several filtrations and pressings to separate the oil from the spermaceti, which is melted and cast into moulds once or twice during the series of pressings. Finally, the wax is warmed and agitated with a little caustic potash solution to remove the last traces of colour and to neutralise traces of acid, and is cast into blocks forming an almost blue-white glistening semi-crystalline solid (Field, Soc. Arts. Cantor Lectures, 1883). It is said that for some purposes it is best not to free it entirely from the sperm oil.

The sp.gr. at ordinary temperatures is about 0.945, but values as divergent as 0.905 and 0.960 have been given, owing probably to irregularities caused by the crystalline structure. The sp.gr. of melted spermaceti at 98° - 99° is from 0.808 to 0.816 as compared with water at 15° (Kehler, Amer. J. Pharm. 1897, 69, 104). The m.p. is from 41° to 49° , but by repeated purifications it reaches 63.5° . Meldrum (Chem. News, 1916, 111, 37), in order to investigate the phenomena of melting and solidifying points and the rise in temperature on setting, selected spermaceti as the substance, and records numerous experiments on it and also on the effect of impurities such as sperm oil, water, glycerin, and oleic acid. The acid value is from 0 to 1.8; saponification value from 120.6 to 124.6; the iodine value of highly purified spermaceti is 0, but values up to 9.3 (by Wijs' method) have been found, caused, as doubt by the presence of sperm oil (Dunlop, J. Soc. Chem. Ind. 1906, 27, 63). It is insoluble in water, and alcohol dissolves little except the coloring matter; it is soluble in boiling alcohol, ether, chloroform,

carbon disulphide; it separates in a crystalline form from the solution in hot alcohol or ether. Bechmann and Kirschner give a long account of the examination of spermaceti for purity (J. Soc. Chem. Ind. 1921, 40, 89A, from Pharm. Zentralh. 1920, 61, 703, 719, 733).

Spermaceti is mainly composed of cetyl palmitate ($C_{18}H_{38}O_2$). It was examined by Chevreul in 1814, and the purified substance was named by him *cétine*; in 1818 he described the alcohol obtained by its saponification (now known as *cetyl alcohol*) under the name *éthol*, formed from the first syllables of ether and alcohol (Recherches, Chim. sur les Corps Gras 1839, 148). The acid with which the radicle of the cetyl alcohol $C_{18}H_{37}OH$ is combined was found later to be palmitic acid. Although spermaceti has a crystalline appearance, it contains compounds other than cetyl palmitate. Heintz (Pogg. Ann. 1854, 92, 609, 93, 536) believes that it yields on saponification stearic, palmitic, myristic, and lauric acids, and the alcohols $C_{18}H_{37}O$, $C_{16}H_{33}O$, $C_{14}H_{29}O$, and $C_{12}H_{25}O$; he named the first, third, and fourth of these *stéthol*, *methol*, and *léthol* in analogy to Chevreul's *éthol*. These very probably exist in the spermaceti as esters of the corresponding acids. He also found another liquid substance in the products of saponification.

Spermaceti is used for making candles which burn brightly and in pharmacy for making ointments. For candle-making the addition of a few per cent. of beeswax or paraffin is advantageous to remove the brittleness of the spermaceti. Spermaceti candles of prescribed composition and properties were formerly used as the standard for measuring the illuminating power of different lights (Young, J. Soc. Chem. Ind. 1891, 10, 185; Met. Gas Referees, *ibid.* 1894, 13, 65).

Sugar cane wax. A waxy substance is produced by the sugar cane, and is noticeable on the rind of some varieties, especially near the nodes; it is most abundant on the violet cane. It was first described by Avequin (Ann. Chim. 1840, [ii.] 75, 218), who named it *cérose*. Cold alcohol removes some colouring matter, chlorophyll probably, but does not dissolve the wax. The purified wax can be obtained by removing the portion soluble in cold alcohol, then dissolving in boiling alcohol, cooling, pressing, driving off the alcohol, and melting. It is dull yellow, hard, and can be powdered; it is insoluble in water, cold alcohol and cold ether; hot ether dissolves it to some slight extent, and deposits it on cooling in small crystalline grains; boiling alcohol dissolves it completely, and the solution on cooling becomes semi-solid, just as does an alcoholic soap solution. It melts at 82° and solidifies at 80° , and its sp.gr. is 0.961 at 10° . When made into a taper it burns with a fine white flame like wax or spermaceti.

Analyses of the wax were made by Dumas (*ibid.* 225) and Levy (*ibid.* 1845, [iii.] 13, 451) who assigned formulae to it on the supposition that it was a single compound, but from Wijnberg's experiments (Het Rietwas en de Mogelijkheid zijner Technische Winning, 1909; J. Soc. Chem. Ind. 1909, 38, 991, 999) the wax appears to contain cetyl alcohol $C_{18}H_{37}O$, and also a substance of a composition corresponding to $C_{18}H_{35}O$, which is neither an ester nor a primary alcohol,

since it yields no hydrogen when heated with soda lime. Prinsen Geerligs (Arch. v. d. Java-Suikerindustrie, 1893, 1, 67) also examined the wax.

In the manufacture of cane sugar the juice is purified by treatment with lime and heating; the resulting muddy precipitate is filtered off and forms a waste product. Wijnberg proposes to extract the wax from this by the use of benzene or other solvents and utilise it (Fr. Pat. 397843, 1908). He finds that the extract from fresh mud contains a large proportion of fatty matters besides the wax, but that in mud which has been kept for some time the fatty matters undergo a kind of fermentation, and are decomposed and a product is obtained approximating more closely to the wax got by scraping the cane. It is stated that extraction of the wax has been undertaken in Java. The subject is treated of very fully in Wijnberg's book mentioned above. J. Soc. Chem. Ind. 1910, 29, 33, deals with a U.S. Patent and gives analytical values.

W. E. Cross (J. Soc. Chem. Ind. 1915, 34, 845, from Intern Sugar J. 1915, 17, 311) found from experiments that by submitting the raw mill juice to centrifugal action a product containing over 50 p.c. of wax was obtained, and thus by one crystallisation from alcohol gave a pure hard product, melting at 82° .

Ucuhuba wax. An investigation of the wax from the fruit of *Myrsine surinamensis*, Roland, was made by Reimer and Will (Ber. 1885, 18, 2011), who found that the chief component was trimyristin, glyceryl trimyristate. The wax obtained by an ether extraction melted at 45° . An account of the seeds of this plant, obtained from an exhibit of the Pará Province of Brazil, is given by Tschirch (Arch. Pharm. 1887, [3] 25, 619), who says that the seeds are known in commerce as *ucuhuba*. Other references are: Valenta (Zeitsch. angew. Chem. 1889, p. 3); Bolton and Hewer (Analyst, 1917, 42, 35).

About 4 tons of ucuhuba wax were exported in 1920 (Dept. Overseas Trade, Report for Brazil, 1921, p. 19). See also *Oruba wax*.

WEED KILLERS. The best weed killer for the purpose of the agriculturist is generally the hoe in some form or other, aided by the sun and wind. To permit of the ready discrimination, by mechanical means, between the crop and the accompanying weeds is one of the most important advantages of regular drilling or planting. It is only in a few cases that the farmer can derive much advantage from the application of chemical methods of destroying weeds, since, as a rule, any means which will destroy weeds, will render the soil, for a time at least, unfitted for the growth of any plant.

For destroying all vegetation, e.g. for keeping garden paths free from weeds, any general plant poison may be used. Of these there are many; indeed any soluble salt, applied in strong solution, will kill plants by producing plasmolysis. In practice, strong solutions of common salt, 10 p.c., i.e. 1 lb. per gallon; dilute sulphuric acid (1 part in 25 to 30 of water); dilute arsenic

phenol (about 1 oz. commercial carbolic acid to a gallon of water); of sodium arsenite (about 1.5 p.c. solution); or of calcium sulphide (made by boiling 1 part of sulphur with 50 parts of water and 10 parts of quicklime) are often used, the liquid being simply applied to the surface of the walks from a watering pot, which should be well painted on the inside. Sulphides, thiocyanates, and sulphites act as effective plant poisons, and to their presence the poisonous action of fresh 'gas lime' is largely due. Many metallic salts act as plant poisons, even in excessively dilute solution. According to Coupin (Compt. rend. 1901, 654) the weakest solutions of the various salts which had an injurious effect upon the growth of the roots of the seedlings of wheat, contained 1 part of the anhydrous salt and the following parts of distilled water:—

Copper sulphate . . .	700,000,000
Mercuric chloride . . .	30,000,000
Cadmium chloride . . .	10,000,000
Silver nitrate . . .	1,000,000
Zinc sulphate . . .	40,000
Lithium chloride . . .	12,000
Calcium iodide . . .	10,000
Barium nitrate . . .	4,200
Borax . . .	1,000
Manganese chloride . . .	1,000
Calcium bromide . . .	400
Calcium chloride . . .	260

The extreme dilution of the copper sulphate, which can produce a poisonous effect, when applied in solution to the roots, is remarkable. In the presence of soil, however, many of these substances, including copper sulphate, are converted into insoluble and harmless compounds.

But the use of these plant poisons in agricultural practice is limited, owing to the difficulty of restricting their action to the weeds. In some countries, where a particular weed has become a scourge, recourse to these drastic measures is sometimes made, e.g. prickly pear in Cape Colony has been destroyed in many districts by the use of sodium arsenite, or of solutions of arsenical sheep dips, 1 or 2 p.c. solution of the former being sprayed over the uprooted plants, which then die, dry, and can afterwards be burnt.

Of more importance to the farmer is the differential or selective poisoning of weeds, by the use of solutions which, while destroying certain weeds, produce no injurious effect upon the crop itself. The best known of such methods is in the destruction of charlock or wild mustard (*Sinapis arvensis* [Linn.] or *Brassica Sinapistrum* [Boiss.]). The method, due to an accidental observation by Girard in France, in 1897, is to spray the barley or oat field infested with the charlock in the spring, when the charlock plants are about 2 or 3 ins. high, with from 40 to 70 gallons per acre of a 3 p.c. solution of crystallised copper sulphate, best on a still, dry, dull day. Unless rain soon follows the spraying, in which case the result is spoiled, it will be found that the charlock plants quickly blacken and die, while the barley or oats and clover (if that be also present) are uninjured. In addition to charlock, known in various districts as 'ketlock,' 'wild mustard,' 'yellow flower,' and in Ireland as 'preahagh,' other cruciferous weeds, of which

'runches' (*Raphanus raphanistrum*) is the most important, can be killed by the same treatment. Ferrous sulphate in 10 or 12 p.c. solution may be substituted for the copper sulphate, but according to experience in Ireland (Leaflet No. 6, Dept. of Agric. and Tech. Instruction for Ireland, 1901) is not so efficient. Cereals, clovers (and most other *leguminosae*) are uninjured by the treatment, but docks and thistles, although not usually killed, are seriously checked in growth.

Various explanations of this differential action of copper and iron sulphate solutions have been offered. Girard ascribed it to the solution being retained by the rough and more or less horizontal leaves of the charlock, while the smooth erect leaves of the cereals would permit of the solution running off. Against this is the fact that other plants with horizontal leaves, e.g. clovers, suffer little damage. Another possible explanation is that interaction between the metal of the copper or iron sulphate and the sulphur compounds which are characteristic of the *cruciferae*, may take place and lead to the destruction of the plant.

A third and probable theory is that the cell walls of the leaves of charlock are thinner or weaker than those of cereals, and more readily permit of plasmolysis being set up, when they are brought into contact with saline solutions applied to the exterior of the leaves. This view receives some support from the fact, observed by Heinrich (Jahresb. für Agricultur-Chemie, 1901, 351), that 15 or 20 p.c. solutions of sodium nitrate, ammonium sulphate, or potassium chloride—substances which cannot exert any chemical toxic effect—are also effective in destroying charlock. Moreover, the importance of a dull, still, dry day for the spraying, which is always shown in field trials, is in accordance with this explanation, for under such conditions, the droplets of the solution, deposited on the leaves of the plant, would retain their original concentration for a longer period than on windy or sunny days when evaporation would be hastened.

The experience of the Irish Department of Agriculture is that from 50 to 70 gallons per acre of a 3 p.c. solution of copper sulphate, under favourable conditions of weather, is the most effective spray for destroying charlock in cereal crops, and that even when the weed has come into flower, it can be successfully destroyed by this treatment, whilst the cereals and clover are uninjured.

Another example of differential plant-killing is afforded in the use of the so-called 'lawn-sand' for the destruction of plantains and daisies in lawns. The active ingredient in lawn-sand is usually sulphate of ammonia, and to be effective the preparation must be applied in relatively large dressings—usually about 4 oz. per square yard (= 1210 lb. per acre) is recommended. The result is that the flat-leaved plants, e.g. daisies and plantains, wither, turn brown and die, while the grasses, though, perhaps, temporarily injured and browned, recover and afterwards grow vigorously. Lawn-sand is generally applied in March and, after its toxic action on weeds, acts as an efficient nitrogenous manure.

A certain amount of indirect 'weed' killing can be achieved by suitable manuring; thus the

growth of grasses is favoured at the expense of admitted leguminous plants, by repeated applications of nitrogenous manures, whilst the opposite effect is produced by application of calcareous, phosphatic, and potash manures with avoidance of nitrogenous ones. But this method is of limited application, and is rarely of service to the farmer. It may, however, be used in the adjustment of the relative proportions of grasses and clovers in a lawn. But for the destruction of the more important and troublesome weeds of the farm and garden reliance has chiefly to be placed upon the mechanical methods of cultivating the soil at the most suitable season.

H. I.

WEINSCHENKITE. A rare mineral found in the Bavarian Oberpfalz in white matted globular deposits and in radiating needles on brown hematite. Is mainly a hydrated phosphate of yttrium and erbium $\text{PO}_4(\text{Er}, \text{Y})_2\text{H}_2\text{O}$, containing small quantities of other rare earths (Henrich and Hiller, Ber. 1922, 55 [B], 3013).

WEISSENFELS LIGNITE RESINS v. RESINS.

WEISSGILTIGERZ or WEISSGÜLTIGERZ v. FREIBERGITE.

WEHRLITE v. TETRADYMYTE.

WELD is the dried herbaceous plant known as *Reseda luteola* formerly cultivated to a considerable extent in France, Germany, and Austria. Its cultivation in this country has nearly ceased, because not only is the quantity of colouring matter it contains very small, but the carriage of the plant, owing to its bulky nature, is expensive. A special interest, however, attaches to weld, for it is said to be the oldest European dyestuff known, and was used by the Gauls and other nations dwelling north of the Alps in the time of Julius Caesar.

The plant attains a height of about 3 feet, is pale brown in colour, and is sold in sheaves like straw. The colouring matter is disseminated throughout the entire plant, but the greater quantity occurs in the upper extremity and the seeds.

Luteolin, the main colouring matter of weld, was examined by Chevreul (J. Chim. Med. 6, 157; Annalen, 82, 53), who obtained it in a crude condition; its isolation in a state of chemical purity was first achieved by Moldenhauer (Annalen, 100, 180), who assigned it to the formula $\text{C}_{15}\text{H}_{14}\text{O}_6$. It was subsequently investigated by Schützenberger and Paraf (Bull. Soc. Chim. 1861, [i.] 18), who proposed the formula $\text{C}_{15}\text{H}_{10}\text{O}_6$, and purified it in a somewhat novel manner which is worthy of mention. Weld was exhausted with alcohol, the extract evaporated, and treated with water, which threw down a dirty greenish precipitate. This was collected, introduced with a little water into a sealed tube and heated to 250°. On cooling the sides of the tube were found to be coated with golden-yellow needles of luteolin, and the impurities had collected at the bottom of the tube to form a resinous cake.

Hlasiwetz suggested that luteolin had the formula $\text{C}_{15}\text{H}_{10}\text{O}_6$, and was isomeric with the paradiacetin, which he obtained during the fusion of quercetin with alkali (Annalen, 112, 186).

For the preparation of luteolin in quantity, Perkin (Chem. Soc. Trans. 1896, 69, 306, 799) suggests weld extract.

300 grms. of the extract dissolved in 3 litres of water is treated with 180 c.c. of hydrochloric acid (33 p.c.), and the mixture is digested at the boiling temperature for some hours. A quantity of a black resinous substance separates, which is collected while hot, and the filtrate, which contains the colouring matter, is allowed to stand for twelve hours. A brown precipitate of impure luteolin is slowly deposited, and is collected, washed, and dissolved in a little hot alcohol. On pouring this solution into ether, the main bulk of the impurity is precipitated, and the ethereal liquid on evaporation yields a yellow residue, which is crystallised from dilute alcohol. The product in addition to luteolin contains apigenin (Chem. Soc. Trans. 1900, 77, 1315), and the latter can only be removed with certainty by the following method:—

The mixture dissolved in boiling glacial acetic acid is treated with a few drops of strong hydrochloric acid; this causes the almost immediate separation of luteolin as hydrochloride, whereas the apigenin remains in solution. The hydrochloride is collected, decomposed by water, and the luteolin crystallised from dilute alcohol.

Luteolin $\text{C}_{15}\text{H}_{10}\text{O}_6$ crystallises in yellow needles or leaflets, m.p. 327°–329° (Perkin), 327° (v. Kostanecki, Rozycki, and Tambor, Ber. 1900, 33, 3410), soluble in alkaline solutions with a yellow coloration. With alcoholic lead acetate it gives a bright yellow precipitate and with alcoholic ferric chloride a green solution.

Luteolin sulphate $\text{C}_{15}\text{H}_{10}\text{O}_6\cdot\text{H}_2\text{SO}_4$, orange-red needles; *luteolin hydriodide* $\text{C}_{15}\text{H}_{10}\text{O}_6\cdot\text{HI}$, orange prisms; *luteolin hydrobromide*

ochre needles; and *luteolin hydrochloride*

(Perkin, l.c.), are readily prepared by the action of the acids on luteolin in the presence of boiling acetic acid. By treatment with water these compounds are quantitatively decomposed into luteolin and acid.

Monopotassium luteolin $\text{C}_{15}\text{H}_9\text{O}_6\text{K}$, fine yellow needles, from luteolin by means of alcoholic potassium acetate, is decomposed by boiling water with separation of luteolin. The sodium compound, $\text{C}_{15}\text{H}_9\text{O}_6\text{Na}$, behaves similarly.

Tetra-acetyl luteolin $\text{C}_{15}\text{H}_6\text{O}_6(\text{C}_2\text{H}_3\text{O})_4$, Perkin (also Herzig, Ber. 1896, 29, 1013), colourless needles, melts at 221°–223° (Perkin), 225°–227° (Herzig). *Tetrabenzoyl-luteolin*

colourless needles, melts at 200°–201° (Perkin).

Dibromluteolin $\text{C}_{15}\text{H}_8\text{Br}_2\text{O}_6$, yellow needles melts at 305°.

By the action of nitric acid on luteolin Rochleder (Zeitsch. für Chem. 1886, 602) obtained oxalic acid, and with fused alkali *protocatechuic acid* and *phloroglucinol*. Digested with boiling 50 p.c. potassium hydroxide solution, phloroglucinol and *acetyl-catechol* are produced (Perkin and Horsfall, Chem. Soc. Trans. 1900, 77, 1322).—

When methylated with methyl iodide luteolin yields, in addition to luteolin trimethyl ether,

Acetyl-methyl-luteolin trimethyl ether (Perkin and Howard).

Luteolin trimethyl ether $C_{15}H_{12}O_6(OCH_3)_3$, lemon-yellow needles, m.p. 161° – 163° , forms a monoacetyl derivative

colourless prisms, m.p. 156° – 158° , and with alcoholic potash gives a bright yellow crystalline salt, which is decomposed by water.

On hydrolysis with alcoholic potash at 170° the trimethyl ether gives *veratric acid*, and *phloroglucinol monomethyl ether*, which was isolated in the form of disazobenzene-phloroglucinol monomethyl ether, orange needles, m.p. 251° – 252° .

Methyl-luteolin trimethyl ether

melts at 191° – 192° , and the monoacetyl derivative $C_{15}H_{10}O_6(OCH_3)_2(C_2H_5O)$ at 175° – 176° . By means of alcoholic potash *veratric acid* and *methyl-phloroglucinol methyl ether* (identified as disazobenzene methyl-phloroglucinol monomethyl ether, orange-red needles, m.p. 198° – 201°) are produced.

By digestion with boiling hydriodic acid *methyl-luteolin* $C_{15}H_{12}O_6$, yellow leaflets, is formed, m.p. about 307° – 309° , which gives an acetyl compound melting at 235° – 236° .

Perkin (l.c.) assigned to luteolin the constitution of a tetrahydroxyflavone

and the more recent synthesis of this colouring matter by v. Kostanecki, Rozycki, and Tambor (l.c.) has indicated that this formula is correct.

When *phloracetophenone trimethyl ether* is condensed with *ethyl veratrate* it gives 2:4:6:3':4'-pentamethoxybenzoyl-acetophenone

and this by long digestion with boiling hydriodic acid (sp.gr. 1.96) is converted into luteolin.

Though luteolin when digested with alcoholic potash and ethyl iodide in the ordinary manner gives only a triethyl ether, owing to the presence of an hydroxyl in the ortho position to the carbonyl group, when an excess of the reagents is employed, luteolin tetraethyl ether

colourless needles, m.p. 153° – 155° , can readily be obtained (Perkin, Chem. Soc. Proc. 1912, 28, 323). Though quercetin pentamethyl ether on nitration readily gives the 6'-mononitro derivative (Watson, Chem. Soc. Trans. 1914, 105, 333), luteolin tetraethyl ether yields in similar circumstances only the tetranitro compound $C_{15}H_8O_6(NO_2)_4(OEt)_4$, colourless prisms, m.p. 155° .

On the other hand, the introduction of only one nitro group can be effected by nitrating mono-bromo-luteolin tetraethyl ether (see below) (Perkin and Watson, *ibid.* 1915, 107, 197). Bromine (4 molecules) in acetic acid yields *bromoluteolin tetraethyl ether perbromide*

$C_{15}H_8O_6(OEt)_4Br_4HBr$, orange-yellow prisms, m.p. 161° (decomp.), and this on boiling with water gives *bromoluteolin tetraethyl ether* and *tetrabromoluteolin tetraethyl ether*.

With bromine (1 molecule) in acetic acid solution, *bromoluteolin tetraethyl ether hydrobromide* $C_{15}H_{10}O_6(OEt)_4Br \cdot HBr \cdot C_2H_5O$, pale yellow hair-like needles, is obtained, which when boiled with water gives *bromoluteolin tetraethyl ether* $C_{15}H_{12}O_6(OEt)_4$, colourless hexagonal plates, m.p. 183° , whereas by brominating luteolin tetraethyl ether with 2 molecules of the halogen in acetic acid solution in presence of sodium acetate, *tetrabromoluteolin tetraethyl ether*, colourless crystals, m.p. 111° – 114° , is formed.

Bromo-6'-nitroluteolin tetraethyl ether

pale yellow rhombs, m.p. 170° – 171° , on reduction in alcoholic solution with stannous chloride and hydrochloric acid, gives *bromo-6'-amino-luteolin tetraethyl ether*

yellow prisms, m.p. 165° – 169° . This forms the hydrochloride

bright yellow needles, which when dried over soda lime become scarlet and melt at 187° (decomp.); with *stannic chloride* it forms the salt $(C_{15}H_{10}O_6NBr)_4H_2SnCl_6$, crimson prisms. By means of sodium nitrite the amino hydrochloride yields in the usual way, crystalline *bromoluteolin tetraethyl ether diazonium hydrochloride*, and from this by boiling with water *bromo-6-hydroxy-luteolin tetraethyl ether*

yellow needles, m.p. 255° , the acetyl derivative of which crystallises in white needles, m.p. 270° – 272° , is produced.

This latter, probably owing to its insolubility, is not readily attacked by hydriodic acid (D 1.7), the first product of the reaction being apparently *bromo-6-hydroxy-luteolin diethyl ether*

the acetyl compound of which melts at 213° . The more drastic action of the hydriodic acid, employing also acetic anhydride, gave a small quantity of a compound crystallising in yellow needles, soluble in alkaline solutions with a yellowish brown colour, and which was probably an impure 6-hydroxy-luteolin—

The acetyl compound melted at 250° – 256° .

When air is aspirated through alkaline solutions of luteolin (and also those of chrysin and apigenin), oxidation does not occur. This property, according to Perkin (l.c.), distinguishes the colouring matters of the flavone from those of the flavonol class, which are readily oxidised by this treatment.

It has already been stated that weld contains a second colouring matter, *isochrysin* (v. PARSLAY).

Dyeing properties of weld.—The importance of weld as a dyestuff in silk and wool dyeing has greatly diminished in consequence of its low colouring power compared with quercitron bark, flavin, and old fustic. This in one respect is unfortunate, because, of all the natural yellow colouring matters, it yields the purest and fastest shades. In conjunction with aluminium and tin mordants it gives very bright pure lemon-yellow colours, and these do not change to an olive or reddish tint as in the case of other vegetable yellows. With chromium and iron mordants weld gives yellowish and greenish olives respectively. For yellow, wool and silk are mordanted with alum and tartar in the usual manner and dyed subsequently in a decoction of weld with the addition of chalk to the dye bath. Weld alumina yellow is to some extent still employed in this country for certain army cloths and braid. For silk dyeing, weld extract is manufactured in small quantity, and is used for the production of yellow and olive colours.

A. G. P.

WELDING (*Soude*, Fr.; *Schweiessen*, Ger.) is the joining of two pieces of metal under the hammer at a sufficiently high temperature.

WELSIUM. The name given by Eder (*Akad. Wiss. Wien. Ber.* 1920, 129, 421) to an element supposed to exist between terbium and dysprosium, of which he has tabulated more than 300 lines between $\lambda 6546$ and 3038 .

WESELSKY'S DYES v. OXAZINE COLOURING MATTERS.

WESTFALITES. Explosives consisting of mixtures of ammonium nitrate and resin, with or without potassium nitrate, v. **EXPLOSIVES.**

WETTER DYNAMITE, WETTEREN POWDER, v. EXPLOSIVES.

WHALE OIL is obtained from the blubber of various species of the genus *Balaena*, viz *Balaena mysticetus*, Greenland or 'right' whale (northern whale oil); *Balaena australis* (southern whale oil); *Balaenoptera longimana*, *Balaenoptera musculus* (common rorqual, the largest of all known animals), *Balaenoptera borealis* (northern or Rudolph's rorqual) finback oil, finner-whale oil, humpback oil; *Neobalaena marginata* (Australian whale), *Rhachianectes glauca*, Cope (Japan). Other cetaceans, the zoological species of which have not been determined yet, or which are identical with the foregoing species, are known as bowhead whale, Californian grey whale, orca or killer whale, beluga or white whale; these are chiefly caught by American whalers in the Northern Pacific. The northern whale oil is the 'train oil' of commerce proper; but this name has become a generic name, and has been extended to all other 'blubber oils' included in this group and even to fish oils (see **OILS, FIXED, AND FATS**).

The blubber of whales caught in the northern sea of Europe was, in the early days of the whaling industry, 'tried' on board the whalers; but in consequence of the low yield, and also of the low quality of oil thus obtained, the whales are now brought into the 'trying' stations situated in Finmarken, on the Lofotes, Faro, Shetland, Hebrides, and in Iceland.

To a large extent the American whalers still try the blubber on board ship and deliver the whale oil into the refineries of New Bedford, Mass., on the east coast, and of San Francisco

Columbia the most modern methods (see below) are now in vogue.

During recent years a very extensive whale oil industry has sprung up in the whaling grounds adjacent to the South African coast, especially to that of Natal. The whale, killed by a gun-shot, is blown up with air so as to float the carcass, which is brought immediately into the trying stations, when the whale is hoisted on to a working platform where the blubber is stripped clean from flesh, and care is taken to leave as little flesh as possible on the blubber. The latter is then cut into strips, which are thrown into chopping machines, whence the comminuted mass is immediately delivered into melting pans, and 'boiled' with steam. Five different qualities of whale oil are produced. The best quality is the oil which first runs off the blubber at the lowest temperature, known in commerce as 'Whale Oil No 0'; it is of a pale yellow colour, and has but a faintly fishy smell. This oil contains a very small quantity of free fatty acids. The best brands are 'water-white,' and are free from volatile fatty acids. On further boiling, the second quality—'Whale Oil No 1'—runs off, it is a little darker in colour, although still pale yellow. Its fishy smell is more pronounced than the oil of the first running.

These two qualities of oil are stored in large vessels, whereby they become clarified while depositing 'stearine,' which is filtered off, pressed in hydraulic presses, and sold as 'whale tallow,' or 'whale stearine,' for soap making.

The residual mass in the boiling pans, together with the flesh of the whale, is cut up into strips or fairly large lumps, and is 'tried down' in a digester under a pressure of 40-50 lbs. The oil classed as 'No. 2 oil' is thus obtained. This oil has a brown colour and a strongly developed fishy smell; its proportion of free fatty acids is considerably higher than in 'oil No. 1'. In some stations 'whale oil No. 2' is made from the blubber residues only, and does not contain any oil from the flesh. Hence it represents a superior article to the 'No. 2 oil.'

The bones are worked up in the same manner, and yield a still inferior quality of oil. Such oil ('whale oil No. 3') is darker still, has a more strongly developed odour, and a high percentage of free fatty acids. 'Whale bone oil' of commerce is, however, not exclusively made from the bones, except in those cases where the product is sold under guarantee as 'bone oil.'

All these operations are carried out with the greatest rapidity and precision recalling the routine of the Chicago packing houses which have served as a prototype for the arrangement of a modern whaling station.

In the old whaling stations where the carcass cannot be handled so expeditiously, the oil remains for a longer or shorter time in contact with the flesh, which rapidly undergoes putrefactive changes. The oil suffers in consequence and becomes dark, and is more objectionable as regards smell and free fatty acids than the preceding qualities. This oil is known in the trade as 'carcass oil,' 'whale oil No. 4.'

The residue remaining after the removal of the oil is worked up for manure, 'whale manure.'

This process is carried out in Newfoundland (at Balena) Pacific coast, and South Africa, where the Government has established several new plants. The carcasses of the whales are there completely used up in the manufacture of oil, 'stearine,' bone meal or bones, and other articles of commerce.

If the whale is landed in a perfectly fresh state, cattle meat can be prepared from the fresh meat, as is being done in Iceland and in the Faro Islands, and in South Africa. Some fresh meat is also consumed by the inhabitants locally (Iceland and Faro Islands).

The 'right whale' oil is of better quality than the 'southern whale' oil. The 'finne whale' oil is of still lower quality. Hence the finner whale was formerly neglected by the whalers, but at present even this kind of whale is eagerly pursued by them along the coasts of Norway and Newfoundland, as also to a small extent on the Asiatic coast of Russia, and the coast of Japan. For the chemical characteristics of whale oil, see OILS, FIXED, AND FATS.

Doherty (J. Roy. Soc. N.S. Wales, 1922, 46, 266) obtained the following values for oils from Pacific whales: sp. gr. at 15.5°, 0.9182-0.9232; $n_D^{15.5}$, 1.471-1.476; acid value, 0.75-5.8, sapon value, 192-199; iodine value, 95-119.

The chemical composition of the whale oil fatty acids has not yet been established satisfactorily. The deposited 'stearine' consists to a large extent of palmitin. The iodine value of a sample of pressed cake examined in the author's laboratory was 37.9. Volatile fatty acids are absent. About 10 p.c. of clupanodononic acid can be isolated from whale oil in the form of its octobromide.

According to Milligan, Knuth and Richardson, who separated the fatty acids by fractional distillation of their methyl esters, a specimen of whale oil fatty acids had the following composition: myristic acid, 4.5; palmitic, 11.5; palmitoleic, 17.0; stearic, 2.5; unsaturated acids (mainly oleic), 36.5; unsaturated acid C_{22} , 16; unsaturated acids, C_{23} , 10; unsaturated acids, C_{24} , 1.5; and unsaponifiable matter, 0 p.c. (J. Amer. Chem. Soc. 1924, 46, 157). E. I. Armstrong and T. P. Hilditch (J. Soc. Chem. Ind. 1925, 44, 180) found in a S. Georgia whale oil that the unsaturated acids comprised myristoleic acid, 1 to 1.5 p.c.; palmitoleic acid, 15 p.c.; oleic acid, 35 p.c.; and highly unsaturated acids with 20 and 22 carbon atoms.

Whale oil is not infrequently adulterated with resin oil, the detection of which is simple. For the recognition of seal oil reliance is mainly placed upon the taste.

The 'water-white' and 'pale' brands of whale oil are used as burning oil, and very extensively in soap-making. The lower qualities are employed for leather dressing. For the characteristics of glycerol from whale oil, see Cocks and Selway (J. Soc. Chem. Ind. 1918, 7, 126 T).

Whale oil is also used as a batching oil or putty, for tempering steel, and as a lubricant or screw-cutting machines. In the hydrogenated form (see HARDENED OILS) it is sometimes used as a substitute for margarine on the Continent. Hydrogenated whale oil yields about 0.9 p.c. of unsaponifiable matter and 0.04 p.c. of cholesterol. The unsaponifiable matter, after removal of the

cholesterol, is optically active $[\alpha]_D^{20} = +5.7$. When crystallised from acetone, whale oils yield a larger quantity of insoluble glycerides than do animal fats, and the glycerides remaining soluble in this solvent have a high iodine value (Buttenberg and Angerhauser, Zeitsch. Nahr. Genussm. 1919, 38, 199).

WHEAT. *Estimation of Rye Flow in Wheat Flour.*—J. König and F. Bartchat (Zeitsch. Nahr. Genussm. 1923, 46, 321) have thoroughly investigated chemical methods for the estimation of wheat and rye flours when present in admixture, and show that the diastase method proposed by several workers (e.g. Amberger, Analyst, 1922, 47, 73), methods dependent on the gluten content, on the solubility of the non-glutenous protein, or on the protein soluble in 20 to 70 p.c. alcohol are not trustworthy for the analysis of the mixed flours. It is shown, however, that the percentage of the total protein soluble in saturated solution of calcium sulphate is constant for each flour, and independent of the actual amount of protein in any particular sample of the flours. Ten grams of the flour are moistened in a 500 c.c. flask with the saturated calcium sulphate solution at the room temperature (0.22 gm. in 100 c.c.), made up to the mark and shaken in a machine for one hour, after which the nitrogen is estimated in 100 c.c. of the clear filtrate and expressed as percentage of the total nitrogen in the flour. Treated in this way, wheat flour shows 29.1 p.c., and rye flour 51.5 p.c., so that the proportion of the two flours may be interpolated from the following table.

Wheat.	Rye.	P.
100	—	29
90	10	31
80	20	33
70	30	35
60	40	38
50	50	40
40	60	42
30	70	44
20	80	47
10	90	49
—	100	51.5

The average experimental error with the method is about 5 p.c., but may be exceeded in the case of flour of unusually high acidity (Analyst, 1924, 49, 187. See also CEREALS, vol. ii. p. 130).

A modification of Fleurent's method for the determination of the baking value of flours has been proposed by Braun (Ann. Falsif. 1924, 87, 269; J. Soc. Chem. Ind. 1924, 43, B 782). The ratio of gliadin nitrogen to gluten nitrogen is used to indicate the quality of the flour.

WHEEL ORE v. BOURNONITE.

WHEATSLATES v. WHEATSTONE.

WHEATSTONE (*Corticeus*, Fr.; *Wetzstein*, Ger.), **OILSTONE**, and **HONESTONE**. Hard, fine-grained rocks, usually highly siliceous in character, used for sharpening or whetting edged tools and also for grinding metals. Rocks of several different kinds are suitable for this purpose, such as hornstone, hornfels, lydian stone, quartzite, sandstone, slate, phyllite, schist, &c. (q.v.). They must possess an evenness of grain and texture combined with a certain degree of friability. If the stone is too hard and tough to wear by friction it becomes

glazed and chipped, and does not present cutting surfaces. At the same time the stone must have a certain degree of firmness and must wear evenly. The cutting power sometimes depends on the presence of minute grains of garnet, rutile, or magnetite distributed through the stone. The chemical composition of materials answering to such a description naturally varies between wide limits, but, as a rule, silica predominates. The following analyses are of I, Novaculite, 'Arkansas stone,' from Arkansas (sp.gr. 2.648). II, Novaculite, 'Ouachita stone,' from Arkansas. III, Novaculite, containing quartz and sericite, from Marquette, Michigan (also P_2O_5 , Li_2O traces). IV, Oilstone (turkey-stone) from Asia Minor. V, Belgian razor-hone from Recht (also P_2O_5 , 0.16, S 0.18, organic matter 0.02; sp.gr. 3.22). VI, Whetstone from Cambrian slates at Lausenstein, Bavaria (also organic matter 1.56).

The *novaculite** of Arkansas is one of the most important whetstones. It is found over a wide area in the vicinity of Hot Springs, occurring as bands a few inches to 15 ft. in thickness, interbedded with sandstones and shales of Lower Silurian age. It has a homogeneous, finely granular structure, and is white with a faint bluish tinge. It is brittle and breaks with a conchoidal fracture; sp.gr. 2.648 (Arkansas stone). Under the microscope it is seen to consist of an aggregate of quartz grains with an average diameter of less than 0.01 mm. The stone is rendered more or less porous by minute rhombohedral cavities, representing crystals of calcite or dolomite which have been dissolved out; and it is on the presence of these cavities that the cutting action partly depends. In the trade two varieties of Arkansas novaculite are distinguished: namely, the more compact 'Arkansas' stone in which the cavities form 0.17-0.25 p.c. of the bulk of the stone; and the more porous 'Ouachita' (or Washita) stone, in which the spaces amount to 5 p.c. The latter has the dull appearance of unglazed porcelain; it is the more abundant and obtainable in larger masses, and is also more in demand. The average of several analyses shows 99.50 p.c. SiO₂, of which 2.2-7.2 p.c. is soluble in a caustic potash solution, and 0.44-1.14 p.c. in a solution of potassium carbonate (L. S. Griswold, *Whetstones and the novaculites of Arkansas*, Ann. Rep. Geol. Survey Arkansas, for 1890, 1892, vol. iii.; W. C. Phalen, *Oilstones of Arkansas*, Min. Res. U.S. Geol. Survey, for 1911, 1912, 2, 843).

The Belgian razor-hones (anal. V) occur as

* This term is now often restricted to the Arkansas novaculite, although it was introduced by E. Kirwan in 1784, from the Latin *novacula*, a sharp knife or stone.

fine-grey slates or phyllites of Gedinien (Devonian) age, and are quarried at several places in the neighbourhood of Vielsalm and Salm-Château in the Ardennes. They are micaceous slates containing innumerable minute garnets (A. Renard, Mem. Acad. Belgique, 1878, 41). The German razor-hones from the neighbourhood of Ober-Ammergau in Upper Bavaria consist of a very compact, pale-coloured quartzose clayey limestone, and occur as beds in Jurassic limestones. They are very brittle with a splintery fracture, and are composed of CaCO₃, 83.57, FeCO₃, 2.67, clayey matter 7.63, quartz 5.96=99.85 (C. W. Gumbel, Geogn. Beschreib. Bayern, 1881, 1). The celebrated Turkey oilstone (anal. IV) is also calcareous, containing SiO₂, 70-75, CaCO₃, 20-25 p.c., with often a little alumina. It is obtained in the interior of Asia Minor and exported from Smyrna. Two varieties are distinguished, the white and the black, the latter being slightly the harder.

In England several stones of a more or less similar character are obtained at various places; e.g. the Charley Forest stone or Whittle Hill hornstone, which is a fine-grained, siliceous, slaty rock worked in Leicestershire. The Welsh oilstone is a somewhat similar material from near Llyn Idwal in North Wales. Devonshire oilstones are obtained from the metamorphosed slaty rocks in the neighbourhood of Tavistock. From Scotland come the Water-of-Ayr stone, snake stone, and Tam o' Shanter hones.

The coarser grained *scythe stones* are made of certain kinds of sandstone. Those from Pike in New Hampshire are the most celebrated, being exported to all parts of the world. This material is a fine grained, thinly laminated, micaceous sandstone (W. C. Phalen, *The scythe-stone industry in New Hampshire*, Min. Res. U.S. Geol. Survey, for 1909, 1911, 2, 616). Scythe-stones have been long worked near Blackdown in Devonshire, and are known as 'Devonshire batts.' They are made from siliceous concretions embedded in sand, probably of Upper Greensand age. Similar scythe-stones are also made at Penzlewood, near Stourton in Wiltshire.

In preparing whetstone for use, the blocks as quarry dressed are sawn into small rectangular slabs with a lapidary's disc charged with diamond powder, and then smoothed down on an iron plate charged with emery. Tools for special purposes, as used by dentists, engravers, watchmakers, jewellers, &c., are ground to the required shape.

Wheels made of Arkansas stone are used for fine metal grinding; and powdered whetstone is used as an abrasive material by instrument makers. See also ABRASIVES.

WHEWELLITE. Hydrated calcium oxalate CaC₂O₄·H₂O, crystallised in the monoclinic system.* It forms small, water-clear crystals which are often twinned in heart-shaped forms resembling those of calcite. There are perfect cleavages, and the material is very brittle; sp.gr. 2.46; H.=2½. The refractive indices and double refraction, $\alpha=1.4900$, $\beta=1.5532$,

$\gamma=1.6497$, $\gamma-\alpha=0.1597$, for sodium-light, are very nearly the same as those of calcite (viz. $\epsilon=1.4862$, $\omega=1.6585$, $\omega-\epsilon=0.1713$). The crystals could therefore be used for the construction of Nicol prisms for polarising apparatus if only they were found of sufficient size or if such could be produced artificially. The mineral is found in coal mines, but at only a few localities, namely, Burgk and Zwickau in Saxony, and Brüx and Schlan in Bohemia. It occurs, together with calcite, dolomite, barytes, &c., in small fissures in the shales and sometimes in the coal itself. Crystals have also been found in a metalliferous vein with tetrahedrite and ankerite at Urbeis in Alsace, and under similar conditions at Freiberg in Saxony. L. J. S.

WHISKEY. The term 'whiskey,' applied to the national beverage of Scotland and Ireland, only came into common use in the latter part of the eighteenth century, and is derived from the Celtic 'uisque-beatha' or 'usquebaugh,' meaning 'water of life,' no doubt in reference to its stimulating properties. A similar signification is seen in the terms applied to strong alcoholic liquors in other countries, as 'aqua vitæ,' and 'eau de vie.' Burns employs the three terms 'aqua vitæ,' 'usquebaugh,' and 'whiskey' synonymously.

The introduction of the manufacture of alcohol into Europe is, as the word suggests, due to the Arabs, but in the grape-growing countries of the south, the spirit is naturally produced chiefly from wine, and in the north, from different kinds of grain, the different materials used giving rise to the distinctive flavours characteristic of the spirits of different countries.

In Scotland the manufacture of whiskey was a subject for legislation as early as the sixteenth century, and extracts from the statutes show that 'aqua vitæ' was not the exclusive product of malted barley, but that unmalted grain was also used in the early days of spirit distillation in Scotland, and this has been the practice in Ireland up to the present day.

In 1805, during the Napoleonic wars, and owing no doubt to the possibility of a shortage in the supply of grain for food, the use of grain for the manufacture of spirits was prohibited throughout the United Kingdom.

In both Scotland and Ireland the pot-still was used prior to the invention of the patent continuous still by Aeneas Coffey in 1831, since when the patent still has been increasingly employed for the manufacture of spirit from a mixture of malt and unmalted grain, and known locally as 'whiskey.' About two-thirds of the potable spirit made in Scotland and Ireland at the present time is of this description. The spirit produced from other materials as molasses, rice, starch, potatoes, dates, currants, &c., is almost invariably distilled from a 'patent still,' and is used chiefly for industrial purposes. When *malt only* is used the whiskey is produced in Scotland chiefly, and in Ireland exclusively, from pot-stills. At the present time (1926) there are 9 distilleries in England; all of which are patent-stills only. In Scotland, out of 124 distilleries, 9 use patent-stills and 115 pot-stills only. In Northern Ireland, only 4 distilleries are at present working, and of these 2 use patent-stills and 2 pot-stills only. In the Irish

Free State, out of 14 distilleries, 2 use patent-stills, one both patent and pot-still, and the remainder pot-stills only. Of the latter, 10 are at present 'silent,' i.e. not working.

In 3 of the distilleries in England, 6 in Scotland, and 2 in Northern Ireland, yeast is manufactured on a large scale as a commercial product. In some instances, yeast is the principal product of manufacture—the spirit produced at these distilleries being really a 'by-product.'

The different characters of the various kinds of whiskey are due to the presence of small amounts of secondary products, sometimes referred to as 'impurities' or 'by-products' (as esters, higher alcohols, &c.), rarely exceeding in the aggregate one-half p.c. of the ethylic alcohol present, but sufficient to impart a distinctive flavour and aroma to the spirit.

These differences in character depend mainly upon (a) the kind and relative proportions of the materials used in the wash; (b) the methods of mashing and fermentation employed; and (c) the type of still used and the manner in which it is worked.

For the processes of mashing, fermentation, and distillation employed in the manufacture of ordinary alcohol, and for a description and diagram of Coffey's patent still, see article ALCOHOL.

This is known as 'silent' or neutral spirit, but grain spirit, distilled from patent stills, when intended for potable purposes, is not so highly rectified as to be deprived of its 'whiskey' character.

In the manufacture of pot-still whiskey in Scotland, barley-malt is practically the only material employed in the mash, whilst in the Irish pot-still distilleries the mash consists of a mixture of barley-malt with unmalted barley or other grain. The proportions vary with a view to securing particular flavours in the whiskey, but a typical mash consists of about four-fifths barley (malted and unmalted), and one-fifth of wheat, oats, and rye, the proportions decreasing in the order of enumeration. Maize is generally excluded from the pot-still whiskeys.

Besides the formation of sugar by the action of diastase during the mashing process, other substances, the exact nature of which is not thoroughly understood, are obtained in solution, from which the secondary constituents of the finished whiskey are both directly and indirectly derived. According to Bell (Select Committee of the House of Commons on British and Foreign Spirits, 1800-1) some of the essential oils naturally existing in the malt and grain, and the empyreumatic and creosotic bodies with which the malt becomes impregnated during the process of drying over peat, anthracite, or coke fires, pass through the operations in a more or less chemically unchanged condition, thus imparting distinctive characters to the whiskey, particularly when the ordinary pot-still is employed for the distillation.

Similarly during the process of fermentation, the conversion of the sugar into ethyl alcohol is accompanied by other chemical changes resulting in the formation of substances which also influence the flavour of the finished whiskey. Of these the principal are the higher alcohols,

WHISKEY.

which have been shown by Ehrlich and others to be due to the splitting up of certain nitrogenous substances (amino acids) produced by the peptonising action of the malt in the mashing process. The ultimate result is affected by the special nature of the yeast, the temperature at which it works, and the time occupied in fermentation.

The simplest form of pot-stills employed in Scotland are heated by direct fire, and have no special means of rectification. The long neck of the still, however, although originally designed simply to prevent particles of the boiling mash being mechanically carried over by frothing or spraying, incidentally has the further important practical use of effecting considerable rectification.

The pot-stills sometimes have their rectifying power increased by means of perforated plates placed transversely in the neck of the still, or by the use of 'purifiers,' pipes or circular vessels cooled by water and fitted between the neck of the still and the condenser.

Some stills are heated by means of steam-jackets or coils instead of direct fire, and this difference in the method of heating is said to have an important influence on the flavour of the whiskey. Certain empyreumatic bodies are thought to be generated by the open fire method, but according to Bell, Schidrowitz, and Thorpe, these are more probably derived from the peat or coke used for heating the malt kilns.

In the manufacture of Scotch whiskey, two distillations only are usually made, first from the 'wash still' from which the whole of the volatile constituents are collected as 'low wines'; and second, from the 'low-wines still,' the distillate from which is collected in three fractions, viz. (1) 'foreshots,' (2) clean spirit or 'whiskey,' and (3) 'feints.' The first and third fractions are added to the low wines of the next distilling period, and so on throughout the distilling season, the residue left in the wash still ('pot ale'), and that in the low-wines still ('spent lees') being run to waste.

The whiskey is generally run off at a strength of 11-25 overproof, but in the Lowlands, where a third distillation or 'rectification' is generally made, the strength of the whiskey distillate is from 40 to 54 overproof.

In Ireland the pot-stills are generally much larger than in Scotland, having sometimes a capacity of 20,000 gallons. The head of the still is shorter, and the still for low wines and feints is provided with a 'lyne arm,' or long pipe which passes through a tub of water, the liquid thus condensed between the head of the still and the worm being conveyed by a 'return pipe' to the body of the still. By this means a considerable degree of rectification is effected.

Three distillations are the rule for Irish pot-still whiskey, and the fractions are more numerous than in the manufacture of Scotch whiskey, consisting of strong low wines, weak low wines, strong feints, and weak feints. The middle or 'whiskey' fraction is also run off at a higher strength than in the Scotch process, viz. from 24 to 30 overproof.

The point at which the collection of foreshots is stopped and that of whiskey commenced, as well as that at which the running of whiskey ceases and the collection of feints begins, is determined by the judgment and

experience of the distiller, but various simple devices are employed for testing the distillate at different stages, as glass floats or hydrometers, specific gravity beads, and samplers for testing the distillate by dilution with water and observing whether the mixture is opalescent or clear.

Scotch whiskeys may be divided into the following five principal classes: (1) Highland malts; (2) Lowland malts; (3) Campbeltowns; (4) Islays; all made from malt in pot stills; and (5) grains, a name given to patent-still whiskeys. *Irish whiskeys* have no corresponding classification, all the 'self' or non-blended whiskeys being sold under distinctive names.

The secondary products, and therefore the character of the spirit, are considerably affected by the strength at which the whiskey is run off. Some of these products (especially esters) suffer partial decomposition in both the wash and low wines stills, whilst others, of higher boiling-point, remain in the stills and are run to waste with the pot ale and spirit lees. More than two-thirds of the secondary products are lost in this manner, only from 10 to 30 p.c. passing into the finished whiskey. (For the recovery and utilisation of the esters left in still residues, see art. RUM.)

It has not yet been found possible to trace any definite relationship between the commercial characteristics of various pot-still whiskeys and their composition as ascertained by analysis, for the reason that the secondary constituents are not individually identified by chemical analysis, but are assessed in groups consisting of members of the same family though in varying proportions, e.g. acids, aldehydes, esters, and higher alcohols.

There is some reason to believe, from the researches of Guareschi and Mosso (on behalf of the Italian Government), Vaughan of Michigan University, and Husz of Sweden, that other bodies may be present due to decomposition of albuminous matter in the grain and having alkaloid properties. They are alleged to be largely accountable for the deleterious effects of spirit drinking, but, if present, they occur in such minute quantities as to elude identification hitherto.

Husz attributed the unusually deleterious character of the spirits drunk in Sweden in a certain year to the use of unsound grain, and Lombroso has shown that an alkaloid having an action like strychnine is generated in decaying maize. Lauder Brunton, whilst attributing much of the harmful effects of new spirit to furfural, also supports the theory that these effects may be partly due to the presence in minute quantities of alkaloidal bodies, especially in potato spirit.

Schidrowitz has determined the percentage of nitrogen in new pot-still whiskeys with the results shown below, but failed to detect the least trace of substances giving alkaloidal reactions. The nitrogen is calculated as NH_3 , and expressed as grams per 100 litres of absolute alcohol—

Highland malts	0.09-0.12
Lowland malts	0.11-0.30
Campbeltowns (malt)	0.08-0.14
Grains	0.03-0.14
American rye whiskeys (matured)	0.25-0.30

No definite evidence was, however, obtained by the Royal Commission on Whiskey, &c., that the deleterious effects attributed to the consumption of spirits are directly due to the presence of poisonous secondary products, and the bulk of the medical evidence was to the effect that the actual amount of the secondary products is so small compared with that of the ethyl alcohol, that the physiological effects produced by them must also be extremely small in comparison with those due to the ethyl alcohol itself. It would appear to follow, therefore, that whiskey derived either from pot or patent still has much the same toxic effect if taken in the same quantity and at the same alcoholic strength.

At the same time, since many substances are known to produce marked effects on the digestive system merely as a result of the sensation produced by their *flavour*, this plays an important part from a dietetic point of view, and the more agreeable flavour of a mature whiskey may exert a favourable mental effect which promotes the

activity of the digestive processes, whilst the unpalatable flavour of new 'silent' or neutral spirits may tend to interfere with digestion apart from the direct effect due to the alcohol itself.

The methods usually employed for the estimation of the different groups of secondary constituents are given in detail in the Minutes of Evidence taken by the Royal Commission on Whiskey and other Potable Spirits, 1908-9, vol. ii. App. Q. xii. Thorpe; see also vol. i. App. F. Schidrowitz.

The following tables give the results of analyses of various kinds of whiskey by Schidrowitz, Tatlock, and Thorpe, expressed in all cases as parts by weight in 100,000 parts by volume of absolute alcohol (e.g. grams per 100 litres).

Schidrowitz and Kaye's results of analyses of 100 samples of the principal classes of *Scotch pot-still whiskey* are summarised in the following table, showing the minima, maxima, and averages—

No. of samples	Description	Total acid	Esters	Higher alcohols (A-M)	Aldehydes	Furfural	Average total 'impurities'

Results of analyses of 5 samples of spirits made in Germany and sold as cheap whiskey in Hong Kong are given on p. 466.

Samples A and B consisted of 'silent' spirit, with an admixture of pot-still whiskey for the purpose of imparting the genuine flavour of whiskey. They are very similar to what is usually sold as 'whiskey' in public houses in England. Samples C, D, and E consisted of highly rectified 'silent' spirit coloured and flavoured to imitate whiskey. The fusel and impurities were much less than is usually found in genuine Scotch and Irish pot-still whiskeys of high commercial quality, while furfural and other aldehydes were practically absent, and there was no evidence that the spirits contained anything of a deleterious nature apart from the alcohol itself.

'Pot-still' and 'patent-still' spirits (The Royal Comm. on Whiskey and other Pot-still Spirits, App. Q. vi., vii., viii.). "An examination

Secondary products	A	B	C	D	E	Average

secondary constituents in the 'pot-still' spirit. Speaking generally, the percentage of every one of the secondary constituents usually determined is greater in the 'pot' than in the 'patent' spirit, but the most marked differences are in the 'higher alcohols' and 'furfural.' 'Patent' spirit contains no furfural when new, although after storage in wooden casks it is sometimes found to contain traces of this substance, but always in much smaller amount than in 'pot still' spirit, in which it is never absent. The low percentage of the 'higher alcohols,' and the absence of all but mere traces of furfural render it a comparatively easy matter to distinguish 'patent' from 'pot-still' spirit. But the variations in the amounts of the secondary constituents in both classes of spirits renders it less easy to estimate the exact proportion of each kind of spirit present in mixtures. Comparing the 'pot-still' spirits among themselves it will be observed that there are considerable variations in both the total amount and in each constituent of the secondary bodies. The Scotch whiskeys generally show a somewhat less total amount than the Irish, and the Speyside, Banffshire, and Highland samples have a rather smaller amount than the Islay and Campbeltown samples. The latter, as well as most of the Irish samples, are mainly 'blending' as distinguished from 'self' whiskeys.

The differences between new and old 'pot still' whiskeys, so far as shown by analysis, are mainly in the increased amounts of the volatile acids and aldehydes, and to a less extent of the esters found in the old spirit when stored in wooden casks. The higher alcohols and furfural appear to remain very much the same. Any changes that occur in 'patent' spirit are of a similar kind.

'Pot-still' whiskey is almost always stored in sherry casks, or in other well-seasoned wooden casks that have formerly contained similar spirit. A large proportion of the increase in the secondary constituents which occur in spirit stored in such casks takes place in the first few months, and is due to a process of extraction of these products absorbed in the wood of the casks from former spirits. This

absorption is to some extent selective. The ethyl alcohol slowly diffuses through the wood of the cask and passes into the air, leaving some of the esters and higher alcohols behind in the wood, which thus becomes more or less charged with the secondary constituents, according to the length of time and other circumstances attending the storage of spirit in the warehouse.

Probably also, especially when the casks are empty, there is some production of acids, aldehydes, and esters by the slow oxidation of alcohols in the wood of the casks.

A comparison of the ordinary 'patent' spirits with British and foreign spirits of high strength which are not usually stored in wooden casks, but in metal drums or vats, shows that the latter spirits contain still less of the secondary constituents, and that the slight changes which occur in ordinary patent spirits do not take place in these high strength spirits. These spirits are used mainly for technical and industrial purposes, and are often of very great purity, although made from molasses, potatoes, and beetroot sugar residues, or other materials not employed for making spirits intended for consumption in this country.

Maturation or ageing.—In addition to the changes above referred to in the secondary constituents due to storing in casks, there are other changes due to the presence of substances not included in the ordinary analysis of spirits, but which have much to do with the difference in flavour of new and old whiskeys. Thorpe, for example, found indications of pyridine bases, allyl alcohol, and allyl aldehyde derived from the peat used as fuel in malting, and acrolein, due either to the fat in the wash extracted from the grain or possibly from the soap which is occasionally added to the contents of the still to prevent frothing. Schidrowitz found in new pot-still whiskey distinct evidence of the presence of pyrrole, phenolic bodies, an alkaline substance (probably an ammonium salt), sulphuretted hydrogen, sulphurous acid, and a trace of nitriles. All of these are readily changed on exposure to air and moisture, as in storage in casks. The pyrrole probably resinifies, the phenols interact with aldehydes, acids, and

Adulteration of whiskey.—Under Sect. 10 of the Licensing Act, 1921, whiskey (like brandy and rum) may not be sold below a strength of 35 p.c. under proof unless the fact of dilution is notified, and the great majority of prosecutions under the Act for the adulteration of whiskey are on account of dilution with water below the legal limit of strength. For the method of calculating the degree of dilution, see art. BRANDY.

Sometimes a neutral or 'silent' spirit made from substances other than grain (as potatoes, beet-sugar residues, &c.) is mixed with sufficient genuine whiskey to give it a more or less whiskey character, and such adulteration is best detected by expert tasting ('degustation') combined with a determination of the secondary constituents and a comparison of the relations which they bear to each other.

Amongst the various substances alleged to have been used for the grosser forms of adulteration may be mentioned creosote, fusel oil,

methylated spirit, sulphuric acid, and salt. Traces of copper, tin, and lead have been found as accidental impurities derived from the still and other apparatus employed.

In consequence of representations made as to the deleterious character of the whiskey sold in public-houses in the poorer class districts of the larger towns in England, Scotland, and Ireland, and at fairs and markets, particularly in the west of Ireland, an investigation into the matter was made some years ago by the Excise Authorities. Nearly 100 samples were taken from all parts of the United Kingdom and analysed in the Government Laboratory, but, apart from the fact that most of these consisted mainly of plain patent-still spirit, no evidence of the presence of the deleterious adulterants above referred to could be found.

The results of analyses (showing the maxima, minima, and averages) are summarised in the following table (Thorpe):—

	Volatile acid	Alde- hydes	Esters	Higher alcohols	Furfural	Total

Average	8.2	11.1	47.8	232.0	1.2	300.3

There is no legal definition of 'whiskey' in the United Kingdom, but numerous suggestions were made by witnesses before the Select Committee on British and Foreign Spirits in 1890-1, and the Royal Commission on Whiskey and other Potable Spirits in 1908-9, differing

essentially in principle and depending chiefly upon the point of view of the witness.

The strictest definition suggested was that 'whiskey' should be manufactured in a pot still exclusively and from certain prescribed materials grown in the country, as malted barley alone in

the case of 'Scotch' whiskey, and malted barley with unmalted grain (barley, wheat, oats, or rye) in the case of 'Irish' whiskey.

Others would admit patent-still spirit, restricting, however, the materials to cereal grains (including maize), and the saccharifying agent to the diastase of malt, whilst in a few cases the extreme view was held that no restriction should be imposed either on the materials used or the process of distillation.

Since much of the barley used in both Scotland and Ireland is of *foreign* growth, the definition of Scotch and Irish whiskey cannot well exclude the use of foreign grain, and therefore maize (which came into use in 1846 immediately after the repeal of the Corn Laws) is not excluded in the manufacture of 'whiskey.'

With respect to the blending of patent-still spirit made from grain with pot-still spirit, it was held that since whiskey (consisting as it does of alcohol and water, with certain by-products derived from malt and grain) does not cease to be whiskey when diluted with water, so the addition of patent still spirit, also made from grain, does not remove the mixture out of the category of 'whiskey.'

After full consideration of all the evidence the Royal Commission of 1908-9 arrived at the following conclusions and definitions —

(1) That the term 'whisky' having been recognised in the past as applicable to a potable spirit manufactured from (a) malt, or (b) malted and unmalted barley or other cereals, the application of the term 'whiskey' should not be denied to the product manufactured from such materials.

(2) That no restrictions should be placed upon the processes of, or apparatus used in, the distillation of any spirit to which the term 'whiskey' may be applied as a trade description.

(3) *Definition* — 'Whiskey' is a spirit obtained by distillation from a mash of cereal grains saccharified by the diastase of malt, that 'Scotch whiskey' is whiskey, as above defined,

distilled in Scotland; and 'Irish whiskey' is whiskey, as above defined, distilled in Ireland.

WILKITE A rare mineral consisting of tantalate and titanate acids, zirconia, silica, cerium, and yttrium earths, thoria, uranic oxide, ferrous oxide, &c., and of interest in containing scandium (Sc_2O_3 , 1.17 p.c.) in relatively large amount. It is a black, brown, or yellow, amorphous mineral resembling euxenite or yttrioantalite in appearance, and has been found, together with monazite, in a feldspar quarry at Impilala, Lake Lagoda, Finland. It supplied the material for Crookes's work on scandium (Proc. Roy. Soc. 1904, A, 80, 516, Phil. Trans. 1908, A, 209, 15). Orthite from the same locality has also been found to contain 0.8-1.0 p.c. of scandia (R. J. Heyen, Sitz. Ber. Akad. Berlin, 1911, 379). More recently, a mineral containing scandium as an essential constituent has been described (v. THORVALLITE). L. J. S.

WILD RICE. A comparison between wild rice (*Zizania aquatica*) and cultivated rice gave the following analyses for wild rice —

No.	Moisture. p.c.	Ash. p.c.	Protein. p.c.	Ether Extract. p.c.	Fibre. p.c.	Starch p.c.	Soluble carbohydrates as dextrose. p.c.
1	7.74	1.09	13.36	0.46	1.39	65.26	2.08
2	7.85	1.38	13.97	0.89	1.41	61.60	3.69
3	8.93	1.17	14.62	0.72	1.94	60.47	2.33
4	7.83	1.25	14.40	0.66	1.29	62.03	2.93

Although these results show a high proportion of proteins in wild rice, both these and the mineral salts present are of a variety unsuitable for dietetic purposes. There is just sufficient vitamin A to prevent xerophthalmia, but not enough to promote growth. Wild rice is somewhat superior to the cultivated variety as regards its content of vitamin B, but still is not an adequate food (C. Kennedy, J. Agric. Res. 1924, 27, 219; Analyst, 1924, 49, 342).

WILKITE v. THAUMASITE.

WILKITE. A mineral consisting of zinc orthosilicate Zn_2SiO_4 , crystallising in the rhombohedral system (with parallel-faced hemihedria). It is abundant at Franklin Furnace,

and Sterling Hill in New Jersey, where it is mined, together with zincite and franklinite, as an ore of zinc (Zn 55.5 p.c.). Here it is usually massive, but a few clear prismatic crystals of a pale amber-yellow colour, and up to 6½ cm. in length, have been found. Some of these have been cut as gem stones. Portions of the better coloured or clearer massive material is also suitable for cutting as gems. The mineral has also been found at a few other localities, but only in sparing amounts. It varies considerably in colour, being yellowish, apple-green, flesh-red, &c.; the lustre is vitreous to resinous; sp. gr. 4.0-4.1; H. 5½. *Troostite* is a variety containing up to 10 p.c. of MnO replacing the zinc.

oxide, and found as large rough crystals at Franklin Furnace. When struck with a hammer or when exposed to the emanations of a radium salt, the mineral displays a brilliant green phosphorescence. Crystals of willemite have been obtained artificially, and have also been observed in slags and in the muffles of zinc furnaces.

WILLESSEN FABRICS AND PAPER v. CELLULOSE.

WILLOW BARKS v. TANNINS.

WILLYAMITE v. ULLMANNITE.

WINE. Wine, strictly speaking, is the fermented juice of the fruit of *Vitis vinifera*. The term *British wines* is applied to beverages made after the manner of wine from substances other than the juice of fresh grapes.

The vine is cultivated for the manufacture of wine in the middle and south of Europe, the northern and southern extremities of Africa, some of the western parts of Asia, the islands of the Atlantic, portions of America—from the Potomac in the north to the centre of Mexico in the south—in California, and in Australia. The number of varieties is very large; but experience shows that the vines employed in particular districts should either be indigenous to those districts or be improved varieties of the indigenous strain. Thus, European vines when tried in America were but partially successful; whilst, on the other hand, American vines transplanted to the Gironde degenerated and yielded no potable wine. The vine grows on chalky, silicious, aluminous, and magnesian soil, best along the borders of rivers, and on ground which, though not itself soaked with water, can constantly attract it from the subsoil.

Vintage and vinification.—The methods of procedure vary with the character of the wine—i.e. whether white or red wine is to be produced. The practice as regards the period of ripeness at which the grape is gathered varies considerably; thus, in the case of champagne, where the greatest attainable paleness is desired, the grapes are gathered before the point of fullest maturity, whereas the wines of Burgundy are vintaged when the grapes produce the deepest colour. Wines from imperfectly-ripened grapes require longer time to mature after manufacture, and, theoretically speaking, the grapes should hang until excessive dryness or danger of frost threatens; but other and conventional considerations, such as colour, have to be taken into account. In exceptional instances, as in the Sauterne district, those berries only are cut out of the bunch which have attained the desired point of ripeness; but the common practice is to gather all the grapes carried by the vines, the vintagers either separating immature and spoiled berries as they proceed, or carrying the whole bulk to a kind of specialist, who performs this part of the labour. Whichever course may be taken, the selected fruit is carried to the press house, and the question then arises whether the stalks are to be removed or pressed with the grapes. In the case of white wines the almost universal practice is to leave the grapes upon the stalks, for the reason that the resulting liquor is almost at once separated from the marc, and before the astringent principle of the stalks can be communicated to it, whereas red wines must be allowed to remain upon

the marc for some time, and the stalks are removed. The commonest mode of separation is to cause the grapes to pass through a series of sieves, by which the stalks are retained. The grapes are now crushed, either by being trodden underfoot in vats or by being passed through machines furnished with grooved rollers, the one thing to be avoided in either case being the bruising of the seeds and stalks if these have not been removed. The next process is pressing. The machines employed for this purpose were formerly boxes, so made that the must was expelled through apertures by superincumbent pressure exerted by a screw; but latterly centrifugal machines have been employed, with a saving of labour and time. In white wines the must is separated as much as possible from the marc before pressing; whilst in the preparation of champagne the grapes are not crushed at all previous to being placed in the press. In pressing grapes for the manufacture of champagne the pressure is so regulated that the juice is separated into four fractions; generally, 4000 kg. of grapes yield a first fraction (cuvée) of 20 hectolitres of juice, second and third fractions of 3 hl. each, and a fourth fraction of 2 hl. The first fraction is the most valuable and yields a wine containing a relatively higher quantity of total acids and free acids (tartaric and malic acids); the presence of these acids increases the resistance of the wine to 'sickness' and to the action of bacteria. The keeping qualities of the wine are also due to the fact that only very small quantities of nitrogenous substances, phosphates, and potassium salts are present. The other fractions of the juice are less valuable, and the wines prepared from them are more readily attacked by micro-organisms (E. Manceau, Ann. Falsif. 1923, 16, 517; J. Soc. Chem. Ind. 1924, 43, B. 227). According to L. Mathieu (Chimie et Industrie, 1923, 10, 847), white wines are liable to the same causes of turbidity as red wines, but the effect is more marked, as a slight haze, imperceptible in a coloured wine, completely destroys the limpidity of the colourless wine. The author classifies turbidity—under which heading he includes all degrees of haze, from the pale bluish fluorescence due to the most minute particles, to actual cloudiness with visible particles—under two headings: (1) normal, i.e. arising in the actual constitution of the wine, such as bacterial infection, cloudiness caused by chilling or heating, or by oxidation of resinous substances or the mutual interaction of the constituents of the wine, and (2) accidental, i.e. caused by some irregularity or oversight in the manufacture or manipulation. As in the case of other wines, one of the most fruitful causes of trouble is the presence of iron in more than insignificant traces. This may arise from the use of unprotected iron vessels. The rigid exclusion of iron vessels, unless the metal be protected in some way from the attack of the acids of the fruit, is essential (J. Inst. Brewing. Abstr. 1924, 30, 234). In the case of red wines the colour is obtained by allowing the juice from the crushing to ferment, after which it is stirred with the grape husks, whereby the requisite amount of colouring matter is dissolved. So much of the must as can be drawn off by this means is run off by that means, and the marc is pressed

the two portions of the must are then added together. The proportion of must depends upon whether the stalks are removed or not; in the former case it is about 95–97 p.c. of the whole, in the latter it may only be 70 p.c.

The following is a summary of analyses by König of a large number of musts of different origin:—

	Specific gravity	Water	Nitro- genous p.c. matter	Sugar	Acid	Other non-nitro- genous matter	Ash
Minimum	1.0690	51.33	0.11	12.89	0.20	1.08	0.20
Maximum	1.2075	82.10	0.57	35.45	1.18	11.62	0.03
Average	1.1024	74.49	0.28	19.71	0.64	4.48	0.40

Fermentation.—The natural fermentation of grape juice is due to the action of various yeasts (*Saccharomyces Ellipsoideus*, *S. Pastorianus*, *S. Marzianus*, &c.) existing on the skin of the grape, and to 'Zymase' and other enzymes present in the juice. Sergent and Rougebief (Compt. rend. 1924, 178, 732; J. Soc. Chem. Ind. 1924, 43, B. 207) have drawn attention to the dissemination of grape yeasts by insects. They concluded from their experiments that certain insects, particularly *Drosophyla*, play an important part in spreading the yeast. White wines are generally fermented at a temperature of 10° or 12° in barrels with only the bung-hole open for the escape of carbon dioxide. Red wines are generally fermented in vats open at the top, on account of the bulk caused by the retention of the husks and the necessity of stirring, an operation variously performed during or at the completed period of fermentation, according to the district. The higher the temperature the sooner the fermentation is finished; at low temperatures a moderate fermentation takes place, which becomes more violent as the liquid becomes warmer, and reaches a maximum at 27°. By the employment of high temperatures a must rich in sugar can be converted into a wine feebly alcoholic, sweet, and yet having tasting properties. Medium musts are best fermented at from 20° to 24°, and this temperature is reached when the fermentation begins at 15°. When fermentation is completed—i.e. after 10 to 14 days—the liquor has become clear, the yeast cells and other suspended matters are deposited at the bottom of the vessel, and the 'young' wine is racked off and allowed to rest for some weeks.

The young wine slowly loses its sugar by after-fermentation, and albuminous substances, colouring matters, together with the acid potassium tartrate, and calcium tartrate, separate out, forming a crust known as *argol* or *argal* (q.v.; also TARTARIC ACID). It is then racked again into clean casks (which are often 'sulphured' before use), fined, if necessary, with isinglass or white of egg, and occasionally with dried blood or with potassium ferrocyanide. When clear it is racked again and sometimes pasteurised before being bottled or stored in casks to mature.

Influence of the 'marc' on wine.—By allowing the skins and stones of ripe grapes to remain in contact with the must, the resulting wine is said to improve in bouquet, &c., and is less liable to become stale and ropy. In order to redden wine with the skins of black grapes the temperature of the wine should be between 15° and 17°. Bad grapes impart to white and red wines a brown colour. Such wines soon become

turbid. Bad grapes and mildewed skins, as well as bad casks and puncheons, precipitate the red colouring matter, so that the wine becomes pale. The following are some of the cases in which the treatment of wine with 'marc' has been successful: Wine which is muddy and cannot be clarified by the ordinary fining agents; wine in which a fining agent has been used which failed to sink to the bottom; wine which has become weak and flat; wine which is assuming or has assumed a black colour; wine having a barrel taste or a by-taste; wine which is 'corked'; wine remaining after casking off; and wine which is obtained by pressing the lees. In cases where the fermentation of new wine has been checked suddenly, the addition of marc prevents the separation of yeast (J. Nessler, Chem. Zentr. 1882, 265; Chem. Soc. Abstr. 1882, 1014). Wines from pressed marc have a greater content of extract, tannin, ash, total and ammoniacal nitrogen, phosphoric acid, sulphate, and chloride than wines from the vat (Hugues, Ann. Falsif. 1925, 18, 347; J. Soc. Chem. Ind. 1925, 44, B. 936).

Composition.—Wine contains alcohol, glycerol, acids, salts, extractive matter, and those principles which give to it its particular colour, special flavour, smell, or bloom (*bouquet*, *Blume*). Whilst some of the constituents can be accurately isolated and described, others can only be detected by the smell.

The principal alcohol is ethyl alcohol. In rare instances some butyl alcohol, and in others amyl alcohol, together with ethylene glycol and isobutyl glycol (Henniger) are present. The quantity of alcohol in natural wines from grapes varies from 6 to 12 p.c. by weight, or from 13 to 26 p.c. proof spirit, but these limits are extended in exceptional cases. The quantity of glycerol is usually from 7 to 14 p.c. of the alcohol present.

The principal acids present are tartaric, malic, and tannic acids, due to the original grape juice, and carbonic, formic, acetic, and succinic acids as products of fermentation. These greatly aid in the preservation of the wine by preventing the formation of fungi. Traces of propionic, butyric, and cenanthic acids also occur in wine, together with acetaldehyde and possibly some of its homologues. Salicylic and boric acids have also been found as natural constituents of wine. As regards the origin of the fixed vegetable acids of wine, H. Brunner points out (Chem. Zentr. 1877, 4) that malic, succinic, glycollic, and oxalic acids—which are found in unripe grapes, together with tartaric acid—may either be formed by direct building up of the molecules in the plant, or their formation may be partly direct and partly indirect.

Tartaric acid occurs mainly as the dextro-variety; lævo-tartaric acid is only of comparatively infrequent occurrence. If tartaric acid is not found—as, for example, in certain samples of sherry—its absence is probably due to its removal by 'plastering,' to which reference is made later on. The amount of free acid in sound wine, reckoned as tartaric acid, varies between 0.3 and 0.7 p.c. (inclusive of volatile acid, which should not exceed 0.15 p.c.); a greater amount than this imparts sourness to the wine.

It can be demonstrated in the laboratory that the first reduction products of carbonic acid are formic and oxalic acids, and that, from the latter, we can (by the action of hydrogen) pass successively through glyoxylic, tartaric, and malic, to succinic acid, and all these acids have been found in the grape in its various stages of growth. The principal reactions may be represented as follows:—

The characteristic smell of wine is said to be due to cenanthnic and other esters. These esters probably confer the bouquets which distinguish one vintage from another. Among them are acetopropyl, butyl, amyl, capryl, butyro-ethyl, caprylo-ethyl, capro-ethyl, and pelargo-ethyl, and the tartaric esters.

According to Jacquemin (Compt. rend. 110, 1140), the characteristic bouquets of wines are due to the special characters of the yeast used in each district. One and the same must fermented with the yeast obtained from several different districts gave wines having the bouquet characteristic of the district from which the particular yeast had come.

Babo states that the bouquet of the wine from Riesling grapes is produced by the action of frost; wines from other grapes also possess a like bouquet if the grapes are frozen. Rommer (Bull. Soc. chim. [in.] 2, 297) fermented the juice of an inferior grape and of hot-house grapes respectively with yeast cultures obtained from the Champagne, Côte d'Or, and Baxy districts, and found that in each case the wines had the bouquet of those from which the yeast has been derived. Certain of the odoriferous principles are no doubt in the nature of essential oils, which have not hitherto been isolated owing to their small amount and extremely unstable character under the influence of heat and air. In order to retain the bouquet, wines should be bottled as soon as they have attained their maximum bouquet.

According to Berthelot, the amount of the esters in wine is, after a certain time, a constant quantity independent of the nature of the alcohols and acids, but a function only of their relative amount: If A be the percentage weight of alcohol in the mixture, a the amount of alcohol equivalent to the total free acid contained in one litre of wine, on the assumption that it is acetic acid (46 alcohol = 60 acetic acid), y the proportion p.c. of a present as ester in one litre of wine when the alcoholic strength of the wine is A , and x be the amount of alcohol present in the compound ethers of one litre of wine; then

$$y = 1.17A + 2.8$$

$$x = \frac{y \times a}{100}$$

The alcohols other than ethyl alcohol present

are left out of the account, but as they are insignificant in amount the error is trifling. This formula affords a mode of judging of the age and genuineness of wines, except in the case of very young wines, or wines which have been recently fortified, the esters in these cases being less than that required by the formula. The maximum esterification is reached in from 4 to 6 years. The alcohol obtained by the decomposition of all the esters rarely exceeds 0.06 p.c. of the wine. (For Thudichum and Dupré's method, *v. their Treatise on Wine*, 203.)

Sugar in wine.—The sugars occurring in must and in wine are dextrose and levulose. Cane sugar is never naturally present in must, but it is sometimes added, as in the case of champagne, but even then it is rapidly transformed into invert sugar. Glycerol is formed as a by-product of the growth of yeast during the process of fermentation, and is accompanied (amongst other changes) by the decomposition of sugar. For every 100 parts of sugar which disappear, from 3 to 4 parts of glycerol are produced. After complete fermentation the sugar seldom reaches 0.5 p.c., but when fermentation is arrested by the addition of alcohol, as in the liqueur wines of France and Spain made from dried grapes, and the sweet wines of Hungary, the sugar may be as much as 20 p.c. or more. In some wines—as *e.g.* Sauternes and sweet Rhine wines—sugar occurs in the form of inositol.

The colouring matters in wine are due to two sources. In white wines—which range from an almost colourless liquid, as champagne, to the deep yellow sherry—the colour is derived from the oxidation of the so-called extractives contained in the juice, which, as was before explained, is separated from the husks as quickly as possible. The grapes of some of the best red wines yield an almost colourless juice if pressed before fermentation, and it is only by the joint action of alcohol and acid upon the husks, stalks, and seeds during fermentation, that the red colour is extracted from the marc. Mulder separated the colouring matter contained in red wines by means of lead acetate, and found it to consist of a substance which was bluish-black in colour and amorphous in structure. It is only sparingly soluble in alcohol, insoluble in water, ether, chloroform, carbon disulphide, oil of turpentine, oil of olives; but soluble in solution of tartaric acid or cream of tartar, and in alcohol containing a trace of acetic acid, the saturated solution showing a blue colour; more acetic acid turns the solution red. It is soluble also in alcohol containing tartaric acid, exhibiting a red colour, but neither of these acids renders it soluble in ether or chloroform. The colour of wine, consequently, depends both upon the amount of colouring matter and the amount of free acid contained in it, as the violet colour becomes redder in proportion to the quantity of free acid acting upon the blue colouring matter.

The colouring matter precipitated by hydrochloric acid—in which it is deposited slowly at the ordinary temperature, but more rapidly on boiling—has been examined by Terrell (Bull. Soc. chim. [ii.] 44, 2). The precipitate always contains a substance resembling ulmic acid, from which the colouring principle may be dissolved

out by alcohol. Thus obtained it forms brittle varnish-like scales, insoluble in water and ether, but readily soluble in alcohol, forming a brownish-red solution with a slightly yellow tinge. Acids change this colour to an intense red, while alkalis give a green coloration, which changes rapidly to a brownish-yellow on exposure to the air (*cf.* O. Griessmayer, *Dingl. poly. J.* 123, 531; *Chem. Soc. Trans.* 1887, 368).

The generally held view that the browning of wines is due to unsound grapes is not correct. The presence of stalks in the fermenting mash contributes appreciably to browning. Very acid wines are particularly prone to browning. The browning is most probably due to the oxidation of tannin-like substances of phenolic character by the action of oxidases or by auto-oxidation, or probably by both processes. It can be prevented, at least to a considerable extent, by immediately pressing the grape mash, but this course is not always possible in practice (H. Müller-Thurgau, A. Osterwalder, and H. Haller, *Landw. Jahrb. Schweiz*, 1923, 37, 215; *Chem. Zentr.* 1923, 74, [iv.] 1010; *J. Soc. Chem. Ind.* 1924, 43, 109).

The browning of wines, which is not only accompanied by a discoloration, but also with a strong turbidity and an unpleasant flavour, can be arrested by the use of sulphur dioxide in the form of potassium metabisulphite, which is added to the juice in the cask before fermentation. The yeasts can withstand without risk quantities of sulphur dioxide towards which *Bacterium gracile*, which effects the decomposition of malic acid at the close of the fermentation, is sensitive. The inhibition of the decomposition of the acid, whether it be temporary or complete, is mainly dependent on the quantity of free sulphur dioxide. Further, the duration of time during which the sulphur dioxide remains in the free condition must be borne in mind, as combination proceeds at different rates with different juices, and therefore the action of the same quantity of sulphur dioxide is not always identical. The commencement of the decomposition of the acid is, moreover, influenced not only by the number of acid-decomposing bacteria present, but also by the nature of the juice and its chemical composition, *e.g.* the content of tartaric acid. From very extensive experiments it was found that the addition of 2-4 grms. of $K_2S_2O_5$ to a hectolitre did not in any case hinder the decomposition of the acid. With 5-6 grms. inhibition was produced with juices rich in tartaric acid, and by the addition of 7.5-8 grms. of $K_2S_2O_5$ to different juices a slight retardation was observed. Quantities of 10-14 grms. of $K_2S_2O_5$ per hectolitre, corresponding with an initial content of free sulphur dioxide of 28 mg. and more per litre, produced complete inhibition of the decomposition of the acid (H. Müller-Thurgau, A. Osterwalder, and H. Haller, *Landw. Jahrb. Schweiz*, 1923, 37, 241; *J. Soc. Chem. Ind.* 1924, 43, B. 109).

The colouring matter of red wines may be estimated with sufficient accuracy for technical purposes by the method of Cari Mantrand (*Bull. Soc. chim.* 1906, [iii.] 35, 1017), by precipitating with lead acetate, decomposing the precipitate with sulphuric acid, filtering, and weighing the residue from an evaporated portion of the

filtrate. The extracted colouring matter may be concentrated and preserved in glycerol for use in confectionery, &c. The maximum amount found was 17.2 grms. per litre in Algerian wine.

According to Willstätter and Zollinger (*Annalen*, 1915, 408, 83; 1916, 412, 195) the colouring matters of wine, *viz.* oenidin and oenin, are derivatives of delphinidin. Oenidin, which has been isolated from the black Italian grape, is the dimethyl ether of delphinidin, and oenin is the monoglucoside of oenidin.

The pigments present in two varieties of American grapes, namely, Norton (*Vitis californica*, *V. labrusca*) and Concord (*V. labrusca*), have been examined by the methods of Willstätter and Zollinger (*Annalen*, 1915, i, 295; 1917, i, 47). The same anthocyanin chloride, $C_{22}H_{22}O_{11}Cl_3H_2O$, has been isolated from both varieties. On hydrolysis, it yields dextrose and an anthocyanidin chloride, $C_{17}H_{15}O_7Cl_3H_2O$. The substances are identical in composition with the oenin and oenidin chlorides obtained by Willstätter and Zollinger from European grapes (*V. vinifera*), but they differ from these substances in that the anthocyanidin contains only one methoxyl group, whereas oenidin contains two. The colour reactions are, moreover, different. The anthocyanin gives with ferric chloride in aqueous solution a purple colour which quickly fades to light brown, and in alcoholic solution an intense blue which changes to purple and finally to wine-red; the anthocyanidin gives with the same reagent both in aqueous and alcoholic solution a momentary purple colour fading to an almost colourless or faintly yellow solution. Evidence of the presence of a diglucoside has also been obtained (R. J. Anderson, *Bio-Chem. J.* 1923, 57, 795; *J. Chem. Soc.* 1924, 126, i, 251).

Some additional colour is imparted to white wine by the tannin extracted from the oak casks during maturing. On the other hand, the natural colouring matter of red wine is reduced by the operation of fining as well as on ageing.

Caramel is frequently used to colour white wines (*e.g.* brown sherry), and occasionally boiled must is added either to the juice before fermentation or to the finished wine. (For foreign colouring matters, *see* below.)

Tannin is derived from the grape skins and stalks, the juice itself being practically free. It is sometimes added, however, to champagne and other white wines to prevent 'scuddiness' or turbidity. The natural tannin of grapes is decomposed by acids or by fermentation into glucose and an acid which is not gallic acid.

The albuminous substances in the grape, which set up the ferment, ought by that action to be removed in the yeast when the fermentation is properly carried out, and should not exceed 4 parts per 1000 of wine, unless the latter has been 'fined.' The albuminous matter is also reduced by 'plastering,' and in old wines it is thrown out together with tannin and colouring matter. In imperfectly fermented wines a certain amount remains, and, in the case of white wines, may again render them liable to fresh fermentation. In red wines this danger is obviated by the presence of the tannin of the

husks, which preserves the albuminous matter from change.

The small quantity of ammonia which is present in grape juice, or is formed during fermentation out of albuminous substances, is, for the most part, precipitated during fermentation as magnesium-ammonium phosphate; a small amount, however, remains, and in some wines is accompanied by minute traces of trimethylamine.

Under the term '*extractives*,' some chemists include all matters other than water, alcohol, and volatile acids; others only those substances which are not volatile up to 100° or 110°. The latter would, however, exclude glycerol, which is properly included amongst the extractives. The composition of certain constituents of the extract which contribute to the smell and taste of the wine is still very obscure. The extractives are, of course, abnormally increased by plastering and addition of sugar (*v. infra*).

The mineral constituents of wine, as found in the ash, are potash, soda, and lime as phosphates, chlorides, carbonates, and sulphates, traces of iron, magnesia, and silica, and occasionally alumina, lithia, and manganese. In pure natural wines the ash rarely exceeds 0.3 p.c., but may be much higher in wines which have been plastered, or to which alkalis have been added to reduce their acidity.

As regards the amount of alcohol, a very comprehensive set of tables, embracing the results of the examination of 133 wines, is given by Thudichum and Dupré (Treatise on the Origin, Nature, and Varieties of Wine, 128-304), from which the following *résumé* is compiled:—

	Strength of wines in degree of proof spirit
German wines, 35 samples . . .	16.2-26.3
French wines, 22 samples . . .	18.0-36.2
Spanish wines, 22 samples . . .	26.7-47.7
Sicilian wines, 6 samples . . .	35.5-31.3
Portuguese wines, 14 samples . .	21.9-46.5
Hungarian wines, 10 samples . .	19.2-22.4
Greek wines, 8 samples . . .	17.8-36.1
Cape wines, 7 samples . . .	36.1-52.7
Atlantic Islands, 3 samples . . .	38.2-31.1
Elba wines, 1 sample . . .	34.99
Australian wines, 5 samples . .	23.5-40.1

Sugar solution wines.—Musts which are too thin, and deficient in sugar, are sometimes concentrated by evaporation (as in Portugal) or, more frequently, a solution of sugar is added. The latter process was first sanctioned by the French minister, Chaptal, and is known as '*Chaptalising*.' A similar process (applied chiefly to acid musts), and known as '*Gallising*,' from its inventor Gall, is also practised in Germany. The must of bad years, which contains a deficiency of sugar and an excess of acid, is mixed with sugar, preferably cane sugar, so as to bring the amount of sugar in the liquid to about 20 p.c., and to reduce the amount of acid to about 2 p.c. Frequently, however, commercial glucose is used, and its addition can frequently be detected in the finished product by its dextrorotatory polarisation (*cf.* Fresenius and Grünhut, *Zeitsch. anal. Chem.* 1921, 60, 188).

The acidity of natural wine can also be

reduced, as suggested by Liebig, by the addition of neutral potassium tartrate, which throws down the free acid, if present as tartaric acid, as acid potassium tartrate. Wine deficient in alcohol and containing much acid may often be improved by adding to it the pressed residue of a succeeding vintage (*cf.* J. Nessler, *Bied. Zentr.* 1884).

A considerable quantity of wine is now made by covering the marc with an aqueous solution of sugar, and allowing the mixture to ferment. The sugar solution contains 18 grms. per litre for every degree of alcohol which it is desired to obtain, and 250 grms. of marc are used for each litre of solution. Analyses of wines prepared in this way by Girard, and of other samples found in commerce, prove that these wines have an approximately definite composition. When they contain from 9 to 10 degrees of alcohol, the proportion of soluble matter, cream of tartar, tannin, and colouring matter is much less than in the ordinary vintage wines. The amount of solid matter varies from 14 to 18 grms. per litre; the amount of cream of tartar is about 2 grms., but not less than 1.6 grm. per litre; whilst the proportion of tannin and colouring matter varies considerably with the nature of the marc. Girard concludes that those wines constitute a highly useful beverage, and can be produced at a very low cost (*A. Girard, Compt. rend.* 95, 227; *Chem. Soc. Abstr.* 1882, 1335).

Plastering of wine.—The practice of adding gypsum or plaster of Paris to must, either before or after fermentation, which prevails in Spain, Portugal, and the South of France, is said to have for its object the reduction of the amount of the water in the juice, and the production, consequently, of a must relatively richer in sugar. The fermentation is much more rapid and complete, and it is alleged that the wine keeps longer when it has been plastered, and that the colour is richer and more lasting. This explanation leaves something to be desired, because the sacrifice of other constituents of juice than water due to absorption by plaster is entirely out of proportion to any gain by the absorption of the water, and the result desired could be attained either by the addition of sugar or the evaporation or freezing out of water. It is probable that the reason for the practice, although unknown to those who employ it, is that gypsum precipitates some albuminous matters which injuriously effect the wine. An obvious advantage to the wine-maker is that it clarifies the wine rapidly and so enables it to be brought sooner to market.

The plaster of Paris, in the form of powder, is either thrown upon the grapes before they are crushed, or added to the must after fermentation has commenced, or even to the finished wine, and the chemical changes that take place vary accordingly. The quantity used is generally from 1 to 2 kilos. to every 100 kilos. of fruit, although sometimes it reaches as much as 10 kilos.

According to Griessmayer, when gypsum is added to the must, it forms, with the tartar present, neutral calcium sulphate and free tartaric acid, which latter reacts on the sulphate, forming bitartrate and acid calcium sulphate. to Borntraeger (*Annali. Chim. Applic.*

1919, 12, 1), the reaction between calcium sulphate and potassium bitartrate is as follows:

It was shown by Bussy and Buignet that the system ($\text{K}_2\text{SO}_4 + \text{C}_4\text{H}_5\text{O}_6$) is converted into $\text{KHSO}_4 + \text{C}_4\text{H}_5\text{KO}_6$. The ash of such wine is neutral, and does not give off carbon dioxide when treated with hydrochloric acid. When gypsum is added to the finished wine, the alcohol prevents its solution, but it carries down many impurities. Kayser (Bied. Zentr. 1881, 632) made experiments which confirmed these conclusions, and states that from the proportions of the ash to the extractive matter, it is possible to declare with certainty whether the wine has been plastered as must or as finished wine; in the first case the ash is disproportionately high, in the other it remains normal. Kayser also states that by the interaction of KHSO_4 and KH_2PO_4 , free phosphoric acid is formed together with neutral potassium sulphate, the former producing the bright colour of plastered red wines. The main change, however, appears to be a decrease in the tartrates and an increase in the proportion of potash and sulphates.

The injurious effects attributed to plastered wines have been the subject of investigation by several commissions appointed by various foreign governments. The most exhaustive inquiry yet made on the hygienic aspect of the subject was by a commission appointed by the French War Department owing to complaints made by the French army in Algeria, where many cases of illness were said to be due to the use of plastered wines. The symptoms are said to be colic, and slight vomiting. The acid potassium tartrate acts towards many reagents in the same manner as free sulphuric acid, and when introduced into the system may have the effect of reducing the alkalinity of the blood.

In view of the inconclusive nature of the evidence, the Commission recommended the maintenance of the regulation forbidding the sale of wines containing more sulphate than that corresponding with 2 grms. of potassium sulphate in the litre, and this limit has been also adopted in Germany, Switzerland, and other countries.

The attempts to 'de-plaster' wine are, from a hygienic point of view, more injurious than the plastering, owing to the use of poisonous barium and strontium salts.

Wine is liable to be affected by a number of injurious ferments, and is especially subject to acetous fermentation, due to *Mycoderma aceti*, which principally attacks the alcohol with production of acetic acid, whilst *Mycoderma vini* attacks principally the cream of tartar and extractive matters. The action of foreign ferments may frequently be prevented by the process devised by Pasteur, which consists in heating the wine for some time to about 70° in absence of air. The bouquet, and in some cases the colour, is thus found to be improved. The heating must be quickly performed, and, as far as possible, out of contact with air.

Numerous substances are employed for the preservation of wine by chemical means as *abrazol* or *asaprol* (the calcium salt of β -naphthol sulphonic acid), *benzoic*, *boric*, and *cinnamic*

acids, *fluorides*, *formaldehyde*, *saccharin*, *salicylic acid*, *sulphurous acid*, and *sulphites*. It should be noted that of these, boric acid, fluorine, and salicylic acid may be present in minute quantities as natural constituents of the wine (*v. infra*).

Sulphuring is carried out either by burning sulphur, sometimes placed on strips of paper, linen, jute, asbestos, &c., in the casks, or by addition to the wine of sulphurous acid or one of its salts. For small works the use of aqueous sulphurous acid or potassium metabisulphite, $\text{K}_2\text{S}_2\text{O}_5$, is most convenient, and in large works that of liquid sulphur dioxide. The colouring matter of red wine is at first bleached by sulphur dioxide, but with proper sulphuring the wine later assumes a more vivid red colour than the non-sulphured wine. In the wine the sulphur dioxide is converted partly into sulphuric acid and into compounds with acetaldehyde and dextrose, the rest remaining in the free state—sulphites are blood- and stomach-poisons, but they are readily and rapidly changed in the human body. Most German wines contain less than 200 mg. of total or 50 mg. of free sulphur dioxide per litre, but with choice wines, which require repeated sulphuring to bring their slow fermentation to a close, as much as 546 mg. per litre has been found; similar results are obtained with sweet sauternes (Journ. Soc. Chem. Ind. 1923, 285 A.). According to Dubaqué, the clouding of white wines after keeping in glass bottles may be due to the action of sulphur dioxide in the wine upon iron silicates of the glass (Ann. Falsif. 1925, 18, 418; J. Soc. Chem. Ind. 1925, 44, B. 821).

The essential oil of black mustard seed (b.p. 150-7°C.) is soluble in alcohol and ether, but in water only to the extent of 1.16 grms. per litre at 15°C. Its antiseptic power, when used in wines, is such that 1 c.c. of a 1 p.c. solution added to 1 litre of wine is efficient, but the amount required varies with certain factors, such as the amounts of sugar and sulphurous acid in the wine, the quantity and vitality of any yeasts present, and the temperature. The souring of red wines, which generally contain no sugar, can be stopped by the addition of 0.8 c.c. of the 1 p.c. solution above mentioned. Essential oil of mustard is about 200 times as active as sulphurous acid and does not affect the odour or flavour of the treated wines. It does not volatilise from the wine, and therefore does not require to be renewed. It has no action on the colouring matters of red wines, fruit juices, caramel, etc. It is estimated by heating 5 c.c. of the preservative on a water bath for 1 hour, with 10 c.c. of ammonia solution and 55 c.c. 0.1N silver nitrate solution in a graduated 100 c.c. flask connected with a reflux condenser. The solution is cooled, diluted to the mark, filtered from the precipitate, and the silver estimated volumetrically in 50 c.c. of the filtrate (P. Malvezin and G. Bidart, Ann. Falsif. 1923, 181, 534; Analyst, 1924, 49, 140; cf. Moreau and Vinet, Ann. Falsif. 1924, 17, 477; J. Soc. Chem. Ind. 1925, 44, B. 49).

Manufacture of 'sparkling' wines.—The effervescence of a sparkling wine is due to the presence of carbonic acid, produced by the fermentation of added sugar. The chief wines of this class (champagne) are produced in the departments of Marne and Haute-Marne, and in

the vicinity of the Moselle and the Rhine. Both white and red grapes are used, and the wine is amber in colour, the depth of tint depending on the vintage and the proportion of dark grapes employed. The vintage is in the early part of October, and in the pressing the must is separated into two portions, that first produced being of the higher quality. The young wine is allowed to ferment until the winter, when it is racked and after the expiration of a month the operation is repeated, when the wine is fined. It is then mixed with a certain proportion of old wine, and the amount of sugar present determined. If necessary, a quantity of cane sugar is added, and the wine is bottled, the bottles being placed horizontally in piles and left at rest throughout the summer. Carbonic acid is formed, together with a quantity of sediment. The pressure of the gas in the bottles can readily be ascertained when desired, by means of a manometer (such as Salleron's modification of Maumené's 'Aphrometre'), and ranges from 5 atmospheres in *grand mousseux* to less than $4\frac{1}{2}$ in *crémant* wine; in ordinary mousseux wine the pressure varies between 4 and $4\frac{1}{2}$ atmospheres. When required for the market, the bottles are first carefully brought into an inclined position, so as to cause the sedimentary matter to fall gradually on to the cork; on removing the clip which holds the cork within the neck the pressure of the dissolved gas forces out the cork, together with the sediment. A certain amount (from 1 to 4 p.c. depending upon the sweetness desired) of liqueur made of fine wine, sugar, and cognac or a stiff spirit, is quickly added, and the bottles are again filled up, corked, and wired.

Dry champagnes—i.e. containing relatively little sugar—are mainly exported to this country; the sweeter varieties being usually consumed in America and on the Continent.

Wines of France. The pre-eminence of France as a wine-producing country is due mainly to its favourable conditions in regard to both climate and soil, and, no doubt, also to the system of small holdings worked by the thrifty and industrious French peasantry. The chief wine-growing district in France is the Gironde, which is practically divided into five portions, viz., the Médoc, the Graves, the Côtes, the Palus, and the Entre-deux-Mers. To these must now be added the wines from the Alsace-Lorraine territory restored to France by the Treaty of Versailles. Although formerly retained almost exclusively for home consumption, they are now (1926) obtainable on the British market. In the Médoc some six or seven different varieties of vine are cultivated.

Most of the red wine is obtained from the Carbenet Sauvignon, Franc Carbenet, Malbec, and Merlot grapes. The vintage usually begins towards the end of September, and lasts about a fortnight. The wines (usually known as 'clarets') are divided into *payan*, *artisan*, *bourgeois*, and *fine growths*, the last group being further sub-divided into what are known as 'crus' or 'classified growths,' named after the place (Château or Commune) where they are produced; e.g. *Château Latour*, *Pauillac*; *Château Lagrange*, *St. Julien*; *Château Margaux*; *Château Cantenac*, &c. The official classification into 'crus' or 'growths' was made so long ago as 1855 by the *Chambre Syndicale des Courtiers*

since when it has not been found necessary to make any alteration. (*Vide 'Bordeaux et ses Vins,' by Feret, Bordeaux, and Encyclopædia Britannica; art. 'WINE.'*)

The chief white wine producing district is to the south of Bordeaux. The principal vines are the Semillon, Sauvignon, and Muscatelle. The vintage is much later than in the Médoc—viz. in the last weeks of October or early part of November, when the grapes have entirely ripened. Three qualities of must are produced: the first and ripest juice yields a sweet luscious wine (*vin de tôle*), mainly consumed in Russia; the second forms *vin de milieu*, the wine usually known as *Sauterne*; the third quality, or *queue*, yields a dry white wine. The principal varieties are *Barsac*, *Sauterne*, *Graves*, and *Bommes*, *Château Latour-blanc*, and *Château Yquem*, which is generally considered to be the premier white wine of France, if not of the world, and in the classification of Sauternes it takes precedence of the 'First Growths,' being placed in a class by itself.

The department of the Pyrénées Orientales produces a considerable quantity of wine, mostly from the Grenache noir and Carignane grapes. The generic name of the wine of the district is *Roussillon*, of which the most esteemed varieties are muscat of *Rivesaltes*, *Maccabeo*, *Malvoisie*, and *Grenache*, which are liqueur wines (the last-mentioned being simply unfermented must preserved by means of added spirit and sulphurous acid, with frequent racking from deposits); and *Randoc*, dry *Malvoisie*, and *Picfoule*. Languedoc also produces a large quantity of wine (*vins du Midi*), much of which is mixed with the wines of the Gironde and of Burgundy; whilst a considerable amount of the rest is distilled to make 'trois-six' and *eau de vie*. Cognac is produced from the wines of the Charente district (*v. BRANDY*).

The Rhône and Saône valleys produce the chief wines of the east of France, which, with the exception of *Hermitage* and the wines of the *Beaujolais*, seldom occur in trade under their own names.

The best qualities of champagne (*v. supra Sparkling wines*) are produced in the department of Marne and Haute-Marne, the chief centres of the trade being at Rheims, Épernay, Ay, Avize, Châlons, and Dizy. The most famous brands are *Ayala*, *Bollinger*, *Cluquet*, *Heidsieck*, *Irroy*, *Mott*, *Mumm*, *Perrier Jouët*, *Pommery-Gros*, and *Roederer*. Large quantities of sparkling wine are produced in the Saumur, in the department of Maine-et-Loire. Sparkling *Saumur* is made from both black and white grapes—the black being the product of the Breton vine, the white that of the Pineau blanc. The wine is made much in the same way as champagne except that, as a rule, the finished product is a mixture of two successive vintages.

The wines of Burgundy (both red and white) are produced in the departments of Côte-d'Or, Yonne, and Saône-et-Loire. The principal red wines are *Mâcon*, *Beaune*, *Le Corton*, *Romanée Conti*, *Chambertin* and *Clos Vougeot*. *Hermitage* when it can be obtained genuine, is a rich wine with purple colour, produced in the department of Drôme. The white wine of Yonne is known as *Chablis*, and is frequently, though incorrectly, described as 'White Burgundy.'

Spain. *Sherry*, the best known of Spanish white wines, is mainly produced in Andalusia, and derives its name from Jerez or Xeres de la Frontera, the chief centre of the trade, and where most of the wine is produced from must or fruit purchased from the growers. Sherries are essentially 'blended' wines, and are divided as regards type or quality into three classes: *Finos*, *Rayas*, and *Cortados*. The *Finos* are 'clean' and 'dry' in character, the *Rayas* being fuller in 'body,' whilst the *Cortados* partake of the characteristics of the other two types. These wines are exported, however, under various other names, as *Amontillado*, *Manzilla*, *Montilla Solero*, &c. Sherries are almost invariably fortified and plastered, and the commoner kinds sulphured in addition, for the British market.

The sweet red wine known as '*tent*,' which is used for ecclesiastical purposes, is mainly obtained from the Rota district. This and the somewhat similar wines from the Tarragona, Valencia, and Alicante districts were formerly sold under the name of 'Tarragona Port,' or 'Spanish Port.' As the result of recent legislation, such descriptions are now illegal, the use of the term 'port' being applicable only to wines the produce of Portugal (*vide infra*).

Portugal. Port is mainly the produce of the rugged and mountainous district of the Alto Douro in the north-east of Portugal. The vintage usually begins at the end of September. The grapes, from which the stalks are removed, are emptied into stone tanks holding from seven to thirty pipes, and are pressed, first by treading and then by means of a beam or screw press. After from 48 to 60 hours' treading the must is left to ferment, drawn off into vats, and mixed with a sufficient quantity of alcohol to prevent acetous fermentation. After the lees are deposited the wine is again racked and mixed with more alcohol, which is usually obtained by distilling wine. If necessary, the wine is sweetened with 'jeropica,' or sweet must preserved with brandy. In the spring it is sent down to Oporto, where it is stored previous to shipment. 'Vintage wines' are those of the same origin, year, and quality, and are kept separately. The other principal types of port are 'Ruby' and 'Tawny.' These are usually blends, the former being intermediate in character between 'Vintage' and 'Tawny' ports. The latter is matured in wood, thus losing much of its deep red colour. Nearly half the wine exported from Oporto is sent to the United Kingdom.

Port first appeared in England at about the end of the seventeenth century, and its consumption in this country gradually increased up to the middle of the eighteenth century, since when it has gradually declined. The disfavour into which port has fallen may be partly due to the manufacture of numerous brands of inferior wines of port character, which may or may not be distinguished by qualifying names, as 'Hamburg Port,' &c.

As the result of representations by the Portuguese Government, definitions of 'Port' and 'Madeira' have been embodied in recent Acts of Parliament. Thus, in Sect. 1 of the Anglo-Portuguese Commercial Treaty Act, 1914, it is laid down: 'The description "Port" or "Madeira" applied to any wine or other liquor, other than

wine the produce of Portugal and the Island of Madeira respectively, shall be deemed to be a false trade description within the meaning of the M. M. Act, 1887.' Still later, in the Anglo-Portuguese Commercial Treaty Act, 1916 (Sect. 1) it is provided that, 'The description "Port" applied to wine the produce of Portugal imported into the United Kingdom after the passing of this Act shall be deemed a false trade description within the meaning of the M. M. Act, 1887, if the wine on importation into the United Kingdom was not accompanied by a certificate issued by the competent Portuguese authorities to the effect that it was a wine to which by the law of Portugal the term "Port" may be applied.' These enactments apply also to British 'made' wines.

The South of Portugal (Torres Vedras and Collares) produces a considerable quantity of a rough kind of claret, and also a white wine known in England as Bucellas Hoek, which is obtained from the Riesling grape.

Italy. It is only within recent years that Italian wines have found much favour in this country, as they were formerly too sweet for the British market and deficient in keeping qualities. These defects have been largely removed by the adoption of more scientific methods of manufacture resulting in an increased popularity. Northern Italy produces *Barolo*, a red, and *Asti*, a white wine, together with a certain amount of sparkling wine. *Montepulciano* and *Chianti* are made in Central Italy; whilst the Neapolitan district yields *Lacryma Christi* and a variety of Malvoisie and good class Muscat wines. The island of Capri produces a good wine of *chablis* character.

Sicily. The chief Sicilian wine is *Marsala* (a white wine of light amber or brown colour, somewhat resembling sherry), obtained from a mixture of selected and thoroughly ripe grapes of the Madeira variety. It is carefully manufactured and is very uniform in quality, although, as a rule, somewhat heavily fortified, but not plastered.

Austro-Hungary. Both white and red wines are made, but those of German Austria are consumed for the most part locally. The best known are from Vöslau and Gumpolds-Kirchen, and the Tyrol. The most famous of Hungarian wines is the Sweet Tokay or Essentia, which is made from the first runnings of the ripe grapes obtained without pressure. Only a small portion is so obtained, and it rarely, if ever, appears in the market. Other varieties of Tokay are known as *Ausbruch* and *Mastos*. *Carlowitz* resembles port in character, and is produced on the banks of the Danube, about 40 miles to the north-west of Belgrade.

The greater portion of the wine produced in Bohemia (now incorporated in Czechoslovakia) is obtained from the province of Melnik, chiefly from the blue Burgundy grape, originally procured from France.

Excellent red wines, resembling Burgundy, are now made in Dalmatia. The most esteemed varieties are *Moscato Rosa*, *Maraschino*, and *Malvasia*.

Germany. The chief wine-producing districts of Germany are Baden, Bavaria, Hesse, the Rheingau, and Württemberg. The celebrated *Steinberg*, *Johannisberg*, *Radesheim*,

Gräfenberg, and *Rauenthal* wines are produced in the neighbourhood of the Rhine, not far from Mainz, which is the centre of the hock trade. The vineyards of Hesse yield *Liebfraumilch*, *Nierstein*, and *Scharlachberg*; *Hochheimer* is obtained from the Maingau. The chief Rhine wine is the Riesling, which is said to be indigenous, and which has been transplanted and successfully cultivated in many other parts of the world as South Africa, Australia, and the United States

of America. The *Moselle* district also produces excellent wines of characteristic but rather weak flavour, which is often artificially enhanced by the addition of tincture of elder flowers.

The chief product is a white wine. A certain amount of red wine is obtained, notably Assmannshausen, from Riesling and mixed grapes. The results of analyses by König of wines from the principal European countries are shown in the following table.

ANALYSES OF EUROPEAN WINES (König).

	Number of analyses	Specific gravity	Grammes per 100 c.c.									
			Alcohol by weight	Extract	Total acid as tartaric	Free tar- taric acid	Cream of tartar	Volatile acid as acetic	Sugar	Glycerol	Nitrogen	Ash

The Atlantic Isles. Grand Canary and Tenerife produce a small quantity of wine, but since the production of cochineal has fallen off on account of the preference for coal-tar colouring matters, vine culture is increasing, and wines of the Madeira type are being made in larger quantity.

Madeira. The best-known varieties of Madeira wine are *Malmsey*, and *Sercial*, the former being a sweet, and the latter a dry wine. It is a white wine, and its characteristic flavour is probably due to the practice of exposing the young grapes to a prolonged process of partial drying by artificial heat, and of heating the wine shortly after its manufacture to a temperature varying from 25° to 45°. Formerly the same condition was obtained by sending the wine a voyage to the East or West Indies and back. Very little red wine is made in Madeira (*vide supra*, under 'Port').

A small quantity of wine is made in the Azores, particularly on Pico, but it is of very indifferent quality, and is mainly exported as low-class sherry.

Cape of Good Hope. Comparatively little wine is now sent to this country from South Africa, although a century ago the importation of Cape wine into the United Kingdom exceeded that from France. The decline was due to vine diseases and insect pests, to faulty manufacture, and to fiscal changes. The best-known wines are *Veldt Burgundy* and *Claret*, *Wynterger Chablis*, *Schoonewicht Hermitage*, *Tafelberg Hock*, and the sweet pale-red *Constantia* produced

near Cape Town. A great increase in the importation of South African wines has occurred since the war, the quantity imported during the last five years immediately preceding the war being only 15,000 gallons, as compared with over 200,000 gallons imported during the corresponding period since the war (1919-23).

Australia. Of late years the amount of wine from Victoria, New South Wales, and South Australia imported into this country has increased enormously. The industry may be said to be still in its infancy, but the most scientific methods and appliances are adopted, and the produce of such vineyards as Albury, Great Western, Highercombe, and Tintara bids fair to rival the best European wines of similar type.

In Australia (as in the case also of South Africa and California) the practice obtains of naming the wines after the well-known European types they more or less resemble in character, as 'Burgundy,' 'Chablis,' 'Hock,' &c., or after the variety of vine originally imported from Europe, as *Riesling*, *Hermitage*, and *Carbenet*.

United States. The manufacture of wine has been firmly established in California. The produce was originally derived from the 'Mission' grape, supposed to have been imported from Mexico by Franciscan monks, but German, French, and Spanish varieties were introduced, and wines in some degree resembling those of these countries (and named after their original types) were made on a considerable scale. The vine has been also cultivated on a large scale in Ohio and Canada and champagne has been

made in the vicinity of Cleveland and Sandusky. Other wine-producing States were New York, Missouri, Illinois, and Pennsylvania. Whilst the finer wines consumed in the United States were obtained from France and Germany, the importation of foreign wines steadily decreased in favour of the home product.

It is understood that at the present time (1926) the national prohibition law prevents the manufacture and sale of wines in the United States.

The following are analyses, by Bigelow (U.S. Dept. of Agric. Bur. of Chem. Bull. 59), of 525 samples of wines manufactured in California:—

Description	Grams per 100 c.c.											
	Alcohol by volume p.c.	Alcohol	Total acids	Extract	Reduc- ing sugar	ids	K ₂ SO ₄

ANALYSIS OF WINE.

The chemical examination of wine is usually restricted to the determination of those constituents which enable an opinion to be formed concerning its purity or freedom from adulteration, but expert tasting is of great importance and microscopical examination of the deposits obtained from wine may afford useful information. For methods based on the latest chemico-physical principles, the work of Baragiola may be consulted (Zeitsch. anal. Chem. 1914, 53, 100; Analyst, 1914, 127).

For the estimation of the *specific gravity* a determination should be made by the bottle or other form of pycnometer and given accurately to four decimal places. Carbonic acid should first be removed by vigorous agitation.

The *results* are usually given in grms. per 100 c.c. or per litre. Koenig (Zeitsch. anal. Chem. 28, 202), however, deprecates this practice, on the ground that for sweet wines, which are liable to differ widely in sp.gr., the results are no longer directly comparable.

The *alcohol* is best determined by the distillation method, the sp.gr. of the weighed distillate being taken and the proportion of alcohol found from tables. For more exact determinations, the volatile acids should be neutralised before distillation.

Detection of cider in wine.—F. Schaffer (Mitt. Lebensm. Unters. Hyg. 1923, 15; Ann Chim. anal. 1924, 6, 88) has devised a method for detecting cider in wine, based on the diminished reducing power of the wine. The following modified procedure is recommended: Forty c.c. of the wine are decolorised by boiling with 3 grms. of pure animal charcoal and filtered, and the filtrate is heated to boiling with excess of precipitated calcium carbonate. After further filtration the cooled liquid is treated, slowly and with shaking, with 8 c.c. of 10 p.c. barium acetate solution, and again filtered. Five c.c. of the neutral filtrate are mixed with 2 drops of 0.2N silver nitrate solution, and, after being made alkaline by addition of 1 c.c. of 0.1N sodium hydroxide solution, are placed in the dark, and the time elapsing before distinct reduction is apparent is noted; the test should be made in duplicate or even triplicate.

With cider the reduction becomes evident in a few minutes, and with wines containing a marked proportion of cider in 10 to 20 minutes; in some cases comparison of the suspected wine with the natural wine of known purity is advisable (Analyst, 1924, 49, 235). If 1 c.c. of concentrated sulphuric acid be mixed (keeping cool) with 5 c.c. of wine and set aside till next day, genuine wine should remain clear (von Fellenberg, Mitt. Lebensm. Hyg. 1925, 16, 55; J. Soc Chem. Ind. 1925, 44, B. 936).

Determination of extract.—The various methods in use for determining extractive matter in wine differ considerably both in principle and in the details of manipulation. The direct method (by evaporation) does not give comparable results unless the sugar of sweet wines and the potassium sulphate in plastered wines are deducted, and not then unless the estimation is conducted under exactly similar conditions.

The French official method of prolonged heating on a water-bath gives low results, owing chiefly to loss of glycerol. The sugar and potassium sulphate are deducted, an allowance of 1 gm. of each per litre being made to cover the amount of these substances assumed to be naturally present in fully fermented wine. The result is known as the 'reduced extract.'

The most exact determination of extract is made by evaporation (at the ordinary temperature) over sulphuric acid *in vacuo*, but as this requires from 3 to 6 days (according to the temperature) it is unsuitable for ordinary commercial use.

By Njegovius' modification of this method, however, the time may be reduced to within the limits of a working day. The wine (5 c.c.) is absorbed by anhydrous sodium sulphate (5 grams) in a tared bottle and dried in a desiccator under diminished pressure, not exceeding 15 m.m.

The German official method is as follows:—

(a) For wines with an extract amounting to not more than 3 grms. per 100 c.c. (ascertained by the indirect method (c) given below): 50 c.c., measured at 15°, are evaporated to a syrupy consistency on the water-bath in a platinum basin of 85 mm. diameter, 20 mm. height, and 75 c.c. capacity, and the residue is dried for 2½ hours in the water oven.

(b) For wines containing from 3 to 4 grms. of extract per 100 c.c. an amount yielding from 1 to 1.5 grms. of residue is taken. For the necessity of using dishes of similar area and surface in order to obtain comparable results, v. Bouillon (Compt. rend. 103, 498).

(c) For sweet wines, or those containing over 4 grms. of extract per 100 c.c., the indirect method of determining the extract from the sp.gr. of the wine after removal of the alcohol is to be preferred (v. Tables in Windisch, Die chemische Untersuchung und Beurtheilung des Weines, 338; abstracted, J. Soc. Chem. Ind. 1898, 280).

The amount both of extract and of alcohol may be determined by Riegler's refractometer method (Zeitsch. anal. Chem. 1896, 27). One grm. of alcohol and of extract in 100 c.c. of wine are found to raise the refraction by 0.00068 and 0.00145 respectively above that of water. Then if a = the refraction of pure distilled water; $(a+b)$ = the refraction of the wine from which the alcohol has been removed made up to the original volume taken; and N = the refraction of the original wine; then the formula
$$\frac{N-(a+b)}{0.00068}$$

gives the weight of alcohol, and $\frac{b}{0.00145}$ that of the extract as grams per 100 c.c. of the wine.

In completely fermented wines the amount of extract is seldom less than 14 grms. per litre. Wines containing less than this amount after removal of the sugar may be suspected of dilution.

After separation of the non-volatile acids, the remaining extract in natural wine is seldom less than 11 grms. per litre, and after separation of the free acids, as a rule, not less than 10 grms. per litre. The mineral constituents are usually about 10 p.c. of the extract.

The free acid is determined by titration with standard potash or soda-solution, using litmus-paper as indicator, and calculating the result as tartaric acid ($C_4H_4O_6$). Carbonic acid should first be expelled, either by heating just below boiling-point (but rapidly so as to avoid loss of acetic acid), or by agitation and subsequent titration in the cold. Volatile acids are determined by distillation in steam, or, since this partially volatilises lactic acid (Windisch, Zeitsch. Nahr. Genussm. 1905, 9, 70), by the difference in the acidity of the wine before and after evaporation to a small bulk, and are expressed as acetic acid ($C_2H_4O_2$). The fixed acids are estimated by difference between the total and volatile acids, or by direct titration of the extract obtained by evaporation *in vacuo*, and are expressed as tartaric acid. In France the acidity is usually given in terms of sulphuric acid (H_2SO_4).

Old wines have an acid reaction, in consequence of the presence of a certain amount of free acid and potassium hydrogen tartrate. A wine not exhibiting this acid reaction tastes flat. For a long time it was believed that the free acid of wine is tartaric acid alone. Nessler's researches have, however, shown that this is not the case. Tartaric and malic acids often occur together, and more frequently the free acid consists of malic acid entirely. Wines containing malic acid alone taste more tart than

those with only malic acid, or a mixture of malic and tartaric acids.

The presence of free tartaric acid in wine does not necessarily show an improper admixture of tartaric acid with the wine. According to Mach and Rolandi, the amount of free tartaric acid in the grape increases in proportion to the degree of unripeness, so that its absence from wine can only occur under certain conditions of ripeness of the grapes employed. Although unripe grapes are frequently used in considerable quantity in wine-making, yet if the ripe grapes are in excess, the potash salts in them are more than sufficient to separate the free tartaric acid in the form of tartar, and this explains the fact that wine so made generally contains no free tartaric acid. A wine may be suspected of having been sophisticated if, with a small amount of free acid, an undue proportion of it is tartaric (J. Nessler and H. Wachter, Bied. Zentr. 1880; Chem. Soc. Abstr. 1880, 775).

The estimation of total tartaric acid, free tartaric acid, potassium bi-tartrate, and tartrates of the alkaline earths (lime and magnesia) is best made by the methods of Halenke and Möslinger, and of Barth (Zeitsch. anal. Chem. 1895, 279-290). These methods were officially adopted by a German Imperial Decree of 1896, an abstract of which is given in the J. Soc. Chem. Ind. 1898, 277. Certain modifications were introduced by Kulisch in 1901. Full details of these, as well as the French official methods, will be found in Post and Neumann's *Traité complet d'analyse chimique appliquée aux essais industriels*, 1910, tome ii. 661. The last three estimations are necessarily empirical, being founded on the assumption that all the bases present in the organic salts of the wine, or as carbonates in the ash, were originally combined with tartaric acid to form bi-tartrates.

A rapid and fairly accurate method of estimating tartaric acid and potassium in wine is that of Kling and Lassieur (Ann. Falsif. 1914, 7, 410; Analyst, 1915, 155). Mathieu (Ann. Falsif. 1919, 11, 80) recommends a method originally described by Pasteur in 1873. For details, see Analyst, 1919, 238. In a later communication he describes the process as follows: about 20 c.c. of the wine are shaken with 20 c.c. of amylic alcohol; the alcoholic layer is separated and shaken with an equal volume of water; the aqueous layer is drawn off, evaporated to dryness, the residue dissolved in 5 c.c. of water and the solution treated with 1 drop of calcium chloride solution (150 grams of crystallised $CaCl_2$ and 40 grams of NH_4Cl per litre) and 2 c.c. of 1-ammonium tartrate solution (20 grms. of the salt per 1 litre of dilute alcohol). A precipitate of calcium racemate forms immediately if the wine contains not less than 0.5 grm. of free tartaric acid per litre (Mathieu, Bull. Assoc. Chim. Sucr. 1921, 38, 352).

Numerous methods have been suggested for the estimation of malic and succinic acids, but they are too uncertain and inexact to be of much value for analytical purposes. The methods for estimating lactic and citric acids are more trustworthy, and the estimation of these is more important, since the former is a constant constituent of wines, and is often the cause of excessive acidity, whilst the latter is never present in genuine wines, except in small amounts.

but is sometimes added to sophisticated wines.

The best methods for estimating *lactic acid* are those of Kunz (Zeitsch. Nahr. Genussm. 1901, 4, 673) and Möslinger (*ibid.* 1901, 4, 1123). *Citric acid* may be estimated by Möslinger's method, weighing as lead citrate, as officially adopted by the U.S. Dept. of Agriculture (Bur. of Chem. Bull. 107, 81).

The determination of *glycerol* in wine has given rise to numerous processes, the best known of which are based upon either extraction by means of alcohol and ether or ethyl acetate or acetone and weighing, or oxidation to and estimation as oxalic acid.

Various methods have been proposed, as steam-distillation under reduced pressure (Bordas and Raczkowski, Compt. rend. 1897, 124, 240); or by conversion into triacetin (Böttger, Chem. Zeit. 1897, 659); or into isopropyl iodide and weighing as silver iodide (Zeisel and Fanto, Zeitsch. anal. Chem. 1903, 549).

The Zeisel-Fanto method always gives low results. Correct values, however, can be obtained when organic acids, such as acetic, propionic, succinic, or tartaric acid, which have a decomposing action on the polyglycerol formed, are added to the reaction mixture. Lowering the concentration of hydriodic acid has no influence on the result: 200 c.c. of wine after treatment with tannin and barium acetate in the usual way are concentrated to about 30 c.c., and diluted with water to 40 c.c. 10 c.c. of the filtrate are then diluted to 50 c.c. with acetic acid, and 5 c.c. of this solution employed for the determination (C. Marchi, Staz. sperim. agrar. ital. 1923, 56, 231; Chem. Zentr. 1923, 94, [iv.] 1011; J. Soc. Chem. Ind. 1924, 43, B. 110).

A method by Rothenfusser, claimed to be more rapid and less laborious and expensive than the official method described below, is given in Zeitsch. Nahr. Genussm. 1913, 26, 535.

The older methods, especially extraction with alcohol and ether, are generally preferred, since, although somewhat empirical, they yield results which are comparable with the enormous amount of similar data acquired by previous observers. It is essential, however, that the exact details of the given methods should be rigidly followed.

The method officially adopted in Germany is as follows, (a) being adopted in the case of dry wines or those containing less than 2 grms. of sugar per 100 c.c.; and (b) for sweet wines containing more than this proportion of sugar.

(a) 100 c.c. of wine are evaporated down to 10 c.c. in a porcelain capsule on a water-bath. 1 gm. of quartz sand is added and milk of lime (40 p.c.) equivalent to 1½–2 grms. CaH_2O , for each gram of extract present, and evaporation continued almost to dryness. The residue is then repeatedly boiled with small quantities of 96 p.c. alcohol, the various extracts being decanted into a 100 c.c. flask, made up to bulk at 15°, filtered, and 90 c.c. of the filtrate evaporated in a porcelain capsule on the water-bath (without boiling). The residue is washed into a stoppered graduated cylinder with small quantities of absolute alcohol until 15 c.c. are collected, then shaken up with three successive

portions of ether (7.5 c.c. each time), and, when clear, the whole (including the rinsings of the cylinder with alcohol-ether, 2:3) evaporated on the water-bath to a syrup, but without boiling. The residue is dried for 1 hour at 100°, cooled, and weighed. The weight in grams, multiplied by 1.111, gives the number of grams of glycerol in 100 c.c. of the wine.

(b) 50 c.c. of wine are heated on the water-bath in a large flask, 1 gm. of quartz sand added, also milk of lime until the dark colour at first produced disappears, and an alkaline odour becomes evident. After cooling, 100 c.c. of 96 p.c. alcohol are added, the precipitate filtered off and washed with alcohol. The filtrate is evaporated and treated as in (a). The factor 2.222 is necessary in this case to obtain the number of grams of glycerol in 100 c.c. of the wine.

A method of estimating glycerol in wine based upon its conversion into acetaldehyde by means of boric acid, the distilled aldehyde being determined by standard silver nitrate solution (Heiduschka and Englert, Zeitsch. anal. Chem. 1921, 60, 161).

For a process involving the use of acetone as solvent, see Beis, Bull. Soc. Chem. 1912, 11, [iv.] 618; Analyst, 1912, 37, 351; Bertainchand, *ibid.* 1913, 38, 368.

The sugar in wine is a variable mixture of dextrose and levulose, and occasionally sucrose. The usual method of examination consists in estimating the total quantity of sugar by titration with copper solution, then ascertaining by the optical method the proportions of the two glucoses and estimating the sucrose after inversion with hydrochloric acid.

Valuable information as to the nature and proportions of the sugars (both natural and added), as well as of other optically active substances introduced for the purpose of sophistication, may be obtained by the use of the polarimeter. Pure wine which still contains unfermented sugars turns the plane of polarisation to the left, whilst perfectly fermented wine either does not polarise at all, or only very slightly to the right. Wines sweetened with commercial glucose may contain considerable proportions of dextrorotatory non-fermentable substances.

It is essential to remove alcohol and colouring matters, and Nessler and Barth show that it is a matter of considerable importance also to remove the tartaric acid present in the wine, and they add, before precipitating with alcohol, a few drops of a strong solution of potassium acetate, thus separating the tartaric acid as potassium hydrogen tartrate.

The wine is carefully neutralised, and the alcohol eliminated by evaporation, the residue filtered, if necessary, and made up to original bulk, decolorized with lead acetate, the excess of lead removed with sodium carbonate or sulphate, and the polarimeter reading corrected for the increased volume due to these additions. The use of bone black should be avoided if possible, and complete decolorization is not necessary if the liquid is clear. Turbidity can be removed by the addition of alumina cream.

A complete scheme, based upon the German official methods (Veröffentl. d. Kaiserl. Gesundheitsamts, 1896, 20, 557) is given in Allen's

Commercial Organic Analysis, 1924, vol. i. 229. The results are obtained from observations in a 900 mm. tube, and expressed in terms of the sugar scale of the Schmidt and Haensch half-shadow saccharimeter.

For the estimation of sugar by Barreswill's (Fehling's) solution, the tannin must first be removed by lead acetate, the excess of lead being precipitated by sodium carbonate or sulphate. Ordinary fully fermented wine usually contains under 0.1 p.c. sugar, and may be decolorised by a small quantity of animal charcoal. Either the gravimetric method (weighing the precipitated copper as CuO) or the volumetric (using as indicator either potassium ferrocyanide or ferrous thiocyanate as recommended by Ling (Analyst, 1905, 182; 1908, 160)) may be used.

Sucrose may be determined by difference between the directly reducing sugars formed as just described, and the total reducing sugar after inversion with hydrochloric acid on the water-bath, deducting one-twentieth of the difference (invert sugar) thus found to obtain its equivalent as sucrose; or the Clerget polariscopic method may be employed, using Herzfeld's modification of the Clerget formula (*v. art. SUGAR*).

The shoots and leaves of the vine, as well as unripe grapes, contain both sucrose and dextrose. The quantity of sucrose in the grapes gradually diminishes to zero as the grapes ripen, whilst the quantity of dextrose reaches a maximum at the period of ripeness. Sucrose, when added to wine, is gradually converted into dextrose, an addition of 5 p.c. being no longer traceable after five months, and 8.5 p.c. being completely transformed in six months. Boiled grape juice contains a substance which, after hydrolysis with acids, reduces Fehling's solution, and might thus be taken for sucrose. No rotation of polarised light can, however, be detected, and the substance is probably glucosan. In the case of wines, therefore, which have been sweetened with boiled grape juice or coloured with caramel, it is unsafe to conclude, from the reduction of Fehling's solution, that sucrose is present unless its presence is also indicated by examination in the polarimeter (O. Klein, *Zeitsch. angew. Chem.* 1924, 37, 111; *J. Soc. Chem. Ind.* 1924, 43, B. 486).

Gum arabic and dextrin, which are sometimes used for sophisticating wines, may be detected by adding to a little of the wine about twice its bulk of the strongest alcohol. If a decided flocculent and viscous precipitate be formed the gum is obtained by evaporating 100 c.c. of the wine to about 5 c.c., and precipitating by the gradual addition of 90 p.c. alcohol. The precipitate is filtered off, dissolved in about 30 c.c. of water, 1 c.c. of strong hydrochloric acid added, and the liquid heated in a flask provided with a long glass tube as a reflux condenser for 3 hours on a bath of boiling water. The sugar thus produced is then estimated in the usual manner by Fehling's solution.

Tannin.—There is no very exact method for the estimation of tannin in wine. That of Neubauer-Löwenthal is recommended, and is described, with modifications, by Fresenius and Borgmann in 'Analyse des Weines,' 1922, p. 74.

Mineral matter is found by cautious incineration of the residue from the evaporation of 50 c.c. of the wine, taking the usual precautions for

separation of carbon from the alkaline salts. Rapid weighing is essential owing to the hygroscopic nature of potassium carbonate.

The determination of the ash (and of several other constituents) of wine containing much sugar is often facilitated and made more exact by eliminating the alcohol and removing the sugar by fermentation.

Wine containing less than 1.3 mineral matter per litre may be suspected unless it can be shown that natural wine from the same district and of the same vintage actually contains so small an amount of inorganic matter. The ratio of mineral matter to extract is, as a rule, about 1 to 10.

Estimation of chlorine in wine.—It is well known to wine falsifiers that chemists lay much stress on the proportion of mineral matters contained in wine, and therefore they frequently add sodium chloride to artificial or adulterated wines in order to increase the extract and to bring the total amount of ash up to the normal quantity. It is also said to hasten clarification and to have a preservative effect. Owing to the volatility of sodium and calcium chlorides on incineration, chlorine is best determined in the wine itself and not in the ash, but the ordinary method of titration is inapplicable owing to the solubility of silver chromate in the free acid of the wine. The chlorine is either precipitated and weighed as silver chloride, or the method of Nessler and Barth may be employed as follows:—50 c.c. of the decolorised wine are acidified with nitric acid, an excess of standard silver solution is added, and then standard thiocyanate solution is run in until a drop of the liquid when mixed on a plate with ferric sulphate solution just shows a pink coloration.

Wines containing more than 0.05 p.c. sodium chloride may as a rule be suspected. Exceptions may occur in the case of wines which have been produced in the neighbourhood of the sea-shore.

Alkaline earths in wine.—The ash of wine always contains calcium and magnesium salts. The amount of calcium (3–11.4 mg. in 100 c.c. of wine) is greatest in young wines and gradually diminishes with age, probably in consequence of the separation of neutral calcium tartrate. The amount of magnesium, on the other hand, remains almost constant and is always in excess of the calcium. The largest amount of magnesium found by Kayser was 24 mg. in 100 c.c. of Malaga wine. The phosphoric acid and magnesia show a constant proportion of 10 : 6, corresponding with the formula $MgHPO_4$ (Kayser, *Chem. Zentr.* 1881; 394; *Chem. Soc. Abstr.* 1882, 121).

Barium and strontium salts are sometimes added, to remove sulphuric acid, in the process of 'deplastering' wines, and are best detected in the ash, which should be taken up with dilute hydrochloric acid, filtered, and the filtrate evaporated to dryness. The dry residue is then examined by the spectroscope. If barium or strontium is present they are determined quantitatively in the usual manner.

Sulphuric acid is precipitated directly with barium chloride in wine acidified with hydrochloric acid, and determined in the ordinary manner.

A normal wine contains not more than 1.4 gm. K_2SO_4 per litre, and when the amount

exceeds 2 grms., the wine may be regarded as plastered or sulphured.

The determination of phosphoric acid is to be effected in the ash by the molybdc method. (For details, see J. Soc. Chem. Ind. 1898, 280.)

The total phosphoric acid may be determined directly (without incinerating the residue) by Grete's volumetric method (Ber. 1909, 42, 3106).

The addition of dicalcium phosphate is sometimes made instead of 'plaster,' and is said to have certain advantages over the use of gypsum.

Nitric acid is sought for by carefully adding a few c.c. of the wine to a solution of diphenylamine in (pure) concentrated sulphuric acid, without mixing, and avoiding rise in temperature. An intense blue colour at the junction of the liquids indicates the presence of nitric acid.

Fresenius (Zeitsch. anal. Chem. 28, 67) finds that in wines containing much sugar a loss of phosphoric acid takes place during the incineration of the residue. A higher result is obtained when the residue is deslagged with alkaline carbonate and nitrate. Destruction of the sugar by fermentation by addition of a very small quantity of yeast leads to the same result.

The assumption that the better kinds of wine always contain more phosphoric acid than the poorer ones is unfounded. At the same time the amount of the phosphoric acid can, in many cases, serve as a valuable means of ascertaining the character of a wine, especially of wines used for medical purposes, or of those of a particular district in which the amount of phosphoric acid varies between definite limits.

Examination for colouring matters.—The principal substances used in red wines are vegetable colouring matters, coal-tar colours (especially fuchsines), and cochineal. White wines are frequently coloured with caramel or coal-tar colours used as substitutes.

According to Jean and Frabot (Ann. Chim. anal. 1907, 12, 52), wines artificially coloured may be distinguished from natural wines by the following test. The wine (50 c.c.) is heated on a water-bath with a little formalin (1 c.c.) and hydrochloric acid (4 c.c.), and when a precipitate is formed the liquid is made alkaline with ammonia and the excess expelled by further heating. The liquid, on cooling and filtration, yields a colourless filtrate in the case of genuine wines, whilst artificially coloured wines yield a coloured filtrate.

(a) *Vegetable colours.*—These are derived chiefly from bilberries, black cherries, elderberries, hollyhock or rose-mallow, poke-berries (*Phytolacca*), indigo and lichens (archil, &c.), alkanet root, Campeachy, Pernambuco, and other dye-woods.

The wine is mixed with an excess of lead acetate and filtered. The colour of the precipitate in a genuine red wine may be greyish-blue, bluish-grey, ash colour, or greenish. If a precipitate is obtained not greatly differing from these colours, the search for other vegetable pigments can give no certain result. The colouring matter of bilberries gives a blue precipitate; mallow and elderberries a green. The colour of *Phytolacca berries* differs from that of red wine by giving a red-violet lead precipitate (see also Lens, Zeitsch. anal. Chem. 1895, 635).

Alkanet-red, which, with Dupré's test (v.

infra), behaves very like the natural colouring matter of wine, is very easily taken up from its solutions by amyl alcohol. On adding to the amyl alcohol a solution of a few drops of olive oil or oil of almonds and evaporating off the alcohol, the oily residue (after washing with water) has a fine red colour, which, on saponification becomes a rich blue, or if the alkanna used was old, a green (Herz, Zeitsch. anal. Chem. 23, 637; Chem. Soc. Abstr. 1890, 311).

Beetroot juice is used in colouring wines for the purpose of concealing the presence of magenta. The absorption-bands of magenta are hidden by those of beetroot, but if a few drops of copper sulphate solution are added to the wine, the beetroot bands gradually vanish and the magenta spectrum becomes visible.

The fresh colouring matters of bilberries and wines are similar but not identical, and, according to H. W. Vogel (Ber. 21, 1746), they are readily distinguished by their absorption spectra after careful neutralisation with ammonia, or, better still, when they are treated with a trace of alum before addition of ammonia. (Care must be taken that the wine is not too concentrated or the ammonia in too great excess.)

Detection of logwood in wine.—When a solution of logwood is treated with manganese dioxide it becomes brown, and this brown liquid, by the action of zinc and hydrochloric acid, gives a colourless solution of hæmatoxylin. This may be detected by the ordinary reagents for that substance, alkalis and their carbonates giving a blue-violet coloration, calcium hydroxide a red-violet, stannous chloride or ammonium molybdate, in a solution slightly acid with nitric acid, a violet coloration. Advantage has been taken of this reaction for the detection of logwood in wines. 20 c.c. of the wine is agitated with 2 grms. finely powdered manganese dioxide, filtered, and the brown liquid treated with zinc and hydrochloric acid, which reduces the oxidised logwood colouring matter to hæmatoxylin. The solution is then divided into several portions, and tested with the reagents given above. Pizzi has examined wines to which other red colouring matters have been added, and although these yield brown solutions with manganese dioxide, the reduced solution does not give the hæmatoxylin reactions. Brazilwood is the only one which has any analogy to logwood, but here also there are differences (Chem. Soc. Abstr. 1881, 761).

Spaeth (Zeitsch. Nahr. Genussm. 1899, ii. 635; Analyst, 1900, 11) gives a table of reactions which may be found useful for the detection of the most commonly used vegetable colours.

(b) *Coal-tar colours.*—In most cases the presence of a coal-tar colour in wine may be recognised by the following methods:—

a. By shaking the filtrate, after with basic lead acetate, with amyl alcohol, or (i.) the wine itself, also (ii.) a portion of the wine acidified with sulphuric acid, and (iii.) a portion made alkaline with ammonia. In the latter case, excess of ammonia should be avoided, as, if more than 3 p.c., the amyl alcohol may remain colourless, although the wine contains a coal-tar colour. The amyl alcohol extract in (i.) and (ii.) may contain natural colouring matter of the wine, but if the colour remain unchanged by ammonia, the presence of a coal-tar colour may

be inferred. The amyl alcohol extract from (iii.) should be shaken up with water and the aqueous solution tested with ammonia or by the wool test.

b. By the wool test, using alum and sodium acetate as a mordant, and adding about 1 p.c. of potassium sulphate in solution.

c. By Cazeneuve's oxide test (Vierteljahrsschrift für Chemie der Nahrungsmittel, 1886, 90; Compt. rend. 102, 52).

The oxides employed are yellow mercuric oxide in the proportion of 0.2 grm. per 10 c.c. of wine; lead hydroxide, containing 50 p.c. of water, in the proportion of 2 grms. per 10 c.c.; and gelatinous ferric hydroxide, containing 90 p.c. of water, in the proportion of 10 grms. per 10 c.c.

Mercuric oxide completely absorbs the natural colouring matter, cochineal and foreign vegetable colours, erythrosin, eosin J, methylene blue, Coupler's blue, and diphenylamine blue. It partially absorbs orange I., safranin, chrysoidine, chrysone, methyleosin, yellow II., red NN, red I., and Ponceau RR. It does not absorb the sulpho-conjugated derivative of rosaniline, Bordeaux red B, Ponceau R, Ponceau B, orange R, orange RRR, orange II., orange RR, tropæoline M, tropæoline II., yellow I., solid yellow, dinitronaphthol yellow, U. S. yellow.

Lead hydroxide completely absorbs the natural colouring matter, cochineal and foreign vegetable colours, methylene blue, Coupler's blue, diphenylamine blue, and erythrosin. It differs from mercuric oxide in not absorbing the rosanilines, and also in absorbing the sulpho-conjugated derivative of rosaniline, Bordeaux red B, the purple red, and soluble red of rocelline.

Ferric hydroxide does not absorb erythrosin, the sulpho-conjugated derivative of rosaniline, Bordeaux red B, purple red, soluble red, and solid yellow. It absorbs the natural colouring matter and foreign vegetable colours, cochineal, and all the derivatives of rosaniline, except the sulpho-conjugated derivative.

Zinc hydroxides and stannous hydroxide behave similarly. The latter retains the natural colouring matter, but does not absorb cochineal or orchi. After the wine has been treated with the hydroxides, the colouring matters must be distinguished by special tests. If the wine is treated with magnesia and hot amyl alcohol, a number of blues which are precipitated by the above-mentioned hydroxides can be isolated and distinguished.

d. Shaking the wine with ether before and after supersaturation with ammonia.

Five to 6 c.c. of the wine to be tested are poured into a glass test-tube of about 20 c.c. capacity, and then three-quarters of its bulk of ether is added. After a few minutes the ether rises to the surface of the wine. If the ether be coloured yellow, and assumes, on addition of some drops of ammonia, a deep-red tint, Campeachy-wood has been used to colour the wine. If the ether becomes red and violet, and remains so even on addition of a large quantity of ammonia, the wine contains colouring matter derived from some of the lichens.

If the red-coloured ether loses its tint on mixing with ammonia, without passing into violet, then only the natural colouring matter of the wine is present. If the red-coloured

ether loses its red tint with ammonia, without imparting any colour to the latter, then fuchsin has been added to the wine. When the ether rises uncoloured, a fresh sample of the wine to be tested is taken, twice its volume of water is poured into it, and half its volume of ammonia added. If the wine now assumes a brownish-red colour, it contains cochineal; if, however, it turns green, then it can be assumed that none of the substances mentioned is present.

e. The formation of isonitriles when aniline derivatives are warmed with potash and chloroform serves for the direct determination in wine of even minute traces of many of the aniline colours. The evolution of the isonitrile is accelerated by adding excess of strong sulphuric acid.

According to A. Dupré, fraudulent colouring matters added to red wines may be detected by dialysis, which is best accomplished by placing in the wine a cube of jelly about $\frac{1}{2}$ -inch side. These cubes are made by dissolving 10 grms. of gelatin in 100 c.c. of warm water, and pouring the solution into a flat dish or mould; from the plate thus obtained the cubes are cut. After 24-48 hours the cube, on examination by transmitted light, will be found to be coloured more or less deeply by any colouring matter present, excepting the natural colouring matter, which penetrates only to a depth of $\frac{1}{8}$ -inch at the most. The colouring matter of alkanet root also penetrates but slowly, whereas rosaniline, cochineal, logwood, brazilwood, indigo, litmus, red cabbage, beet-root, *Malva sylvestris*, and *Althea officinalis* penetrate rapidly into jelly (Chem. Soc. Trans. 1880, 572).

The nature of the colouring matter may be determined either by the colour of the jelly or spectroscopically, or by the action of dilute ammonia, which turns cochineal purple, logwood brown, red cabbage dark green, and decolorises rosaniline (v. SPECTRUM ANALYSIS).

Bordeaux verdissant or 'colorant introuvable' is a mixture of acid fuchsin with methylene blue and diphenylamine orange, the two latter colours being used to produce a green which becomes visible on decolorising the Bordeaux red with ammonia, thus simulating the effect of ammonia on natural red wine. The diphenylamine orange can be extracted with amyl alcohol, the acid fuchsin detected by Girard's mercuric acetate test, and the methylene blue by dyeing cotton fibre.

A substance known as *Tintura por los vinos* is said to have been largely used for colouring certain Spanish wines. It is alleged to contain Biebrich red, sodium sulphate, and arsenious oxide. The presence of arsenic, if a fact, is of special importance.

The methods employed in the Paris Municipal Laboratory for the investigation of the colouring matters in wine will be found in Girard and Dupré's 'Analyse des matières alimentaires.'

Removal of added colouring matter from wine.—So much artificially-coloured wine is confiscated in certain districts in Italy that the authorities are considering the advisability, in the interests of economy, of merely removing the added colouring matter from the wine instead of denaturing the latter before returning it to the owners. For effecting this removal the following methods may be employed: (1) Addition

to the wine of must, thus causing a fresh alcoholic fermentation; (2) addition of young wine, the proteins of which may form insoluble compounds with the colouring matter; (3) clarification by means of egg albumin, fish glue gelatin, &c.; (4) keeping the wine for some time, with repeated transference. The colouring matter most commonly used is 'vinolin,' a mixture of Bordeaux B, Bordeaux R, and Poncau RRR, which may be eliminated by re-fermentation of the wine in presence of vinasse (F. Sourti, *Annali Chim. Appl.* 1923, 13, 194-200; *J. Soc. Chem. Ind.* 1923, 42, 993 A).

Detection and estimation of *preservatives* most commonly used in wine. *Abrastol* or *asaprol* (calcium α -monosulphonate of β -naphthol) is a white or slightly reddish scaly powder readily soluble in water and alcohol, and decomposing at 50°. It is extracted from alkaline solution by amyl alcohol, the extract evaporated to dryness, and the residue tested by Sinibaldi's method (*Mon. Sci.* 1893, [iv.] 7, 842; U.S. Dept. of Agric. Bur. of Chem. Bul. 59, 91).

Boric acid (according to Baumert, *Ber.* 21, 3290) is naturally present in many wines as well as in the leaves and tendrils of the grape-vine. It is detected in the ash by extracting with a large excess of strong hydrochloric acid, and testing with turmeric paper. For its quantitative estimation, see Windisch, *Die Chemische Untersuchung und Beurtheilung des Weines*, 235.

Fluorides are strongly antiseptic and are usually employed in very small quantity in the form of the ammonium or sodium salts which are soluble in water. The fluorine is precipitated as calcium fluoride from alkaline solution by means of calcium chloride, and the precipitate, after filtering, washing, drying, and heating in a platinum crucible, is tested by means of the 'etching' test. A blank experiment should be made with the reagents employed. For *fluoborates* and *fluosilicates* the ash containing the calcium salts is extracted with dilute acetic acid and filtered. The filtrate contains the boric acid which, if present, is detected as above. The calcium fluoride and silicate remain in the insoluble portion, and can be detected by the usual methods (*v. Bull.* 59, 63, U.S. Dept. of Agric. Bur. of Chem.).

For detecting *saccharin* (which is used as a preservative as well as a sweetening agent), the wine (about 100 c.c.) is shaken up with a mixture in equal parts of ether and light petroleum, and the extract, after evaporating off the solvent, is fused with sodium hydroxide and tested by means of ferric chloride for salicylic acid. It is assumed, of course, that the absence of salicylic acid in the original wine has been proved and the presence of saccharin indicated by the sweet taste of the residue from the ether extraction.

The estimation of the saccharin may be made by acidifying (if necessary) with phosphoric acid, extracting with ether as above, and fusing the evaporated residue with a mixture of sodium carbonate and nitre, precipitating the resulting sulphate with barium chloride and calculating the saccharin from the weight of barium sulphate obtained ($\text{BaSO}_4 \times 0.785 = \text{saccharin}$).

Saccharin may also be estimated by hydrolysing the residue from the ether extract with hydrochloric acid, and estimating the ammonia

thus formed by distillation into standard acid (Proctor, *Chem. Soc. Trans.* 1905, 242).

Salicylic acid is best sought for by agitating the wine with carbon disulphide or a mixture of equal volumes of ether and light petroleum (taking care to avoid an emulsion), evaporating down and testing the residue with ferric chloride. If much more than 100 c.c. are used, a faint colour may be occasioned by other substances giving a similar reaction and present as normal constituents of the wine.

An approximate estimation of the quantity of salicylic acid may be made colorimetrically, by comparing the colour given by an alcoholic solution of the residue after ether extraction with that yielded by standard alcoholic solution of salicylic acid of known strength, using, if possible, a liquid similar to that under investigation.

Sulphurous acid and sulphites.—Wine will absorb as much as 0.36 grm. of sulphurous per litre when it is shaken in a barrel in which sulphur has been burnt, and if the treatment is repeated the sulphurous acid may reach 0.5 grm. per litre. Sulphur is burnt in the barrels to prevent the formation of mildew, and sulphites are sometimes used as a preservative. Much of the sulphurous acid is combined with aldehyde when it is considered to be much less objectionable than in the free state.

Sulphurous acid is determined by distilling a portion of the wine, to which phosphoric acid has been added, in a stream of carbon dioxide, receiving the distillate in solution of iodine, and determining the sulphuric acid thus formed. The details of the method are as follows (*B. Haas, Ber.* 15, 154): the wine, to which 5 grms. of syrupy phosphoric acid have been added, is distilled in a current of carbon dioxide, and the distillate is collected in a suitable apparatus (a bulbous U-tube) containing 50 c.c. of iodine solution (containing 5 grms. pure iodine and 7.5 grms. potassium iodide per litre), thus oxidising the sulphurous acid. As soon as the distillate amounts to about half the original volume of the wine used, the contents of the U-tube are washed out, acidified with hydrochloric acid, precipitated with barium chloride, and the barium sulphate washed, dried, heated to redness, and weighed. This method gives very good results. The sulphurous acid may also be oxidised by means of hydrogen peroxide, using barium peroxide, and weighing as barium sulphate (Levi, *Ann. Falsif.* 1913, 6, 5; *Analyst*, 1914, 87).

Opinions vary as to how much sulphurous acid a wine may contain. According to the medical faculty of the University of Vienna, not more than 8 mg. per litre should be allowed, whereas other authorities regard 80 mg. as not an excessive amount. In France and Switzerland the maximum limit is fixed at 200 mg. of SO_2 per litre, of which, in France, not more than 30 mg., and in Switzerland, not more than 20 mg. should be 'free' or uncombined.

Poisonous metallic substances in wine.—Traces of arsenic may be present owing to the use of impure coal-tar colours (acid fuchsine, &c.), and commercial glucose. Copper and mercury may be due to the compounds used as insecticides and fungicides, but are, no doubt, largely removed in an insoluble form during the process of fermentation.

mentation. Lead has been traced to the use of litharge to mask acidity and to lead shot used for cleaning bottles. Zinc is often present in appreciable quantities when the wine has been stored in vessels of unalloyed zinc. These metals may be detected and estimated by the usual methods.

Hydrocyanic acid may be present in wine to which potassium ferrocyanide has been added to remove the iron. For its detection and estimation, see Mach and Fischler (Zeitsch. Unters. Nahr. Genussm. 1924, 47, 329; Reichard, *ibid.* 1924, 47, 339; Zeitsch. angew. Chem. 1924, 37, 957).

Alum is occasionally present in the coal-tar colours employed, and is sometimes added to wine as a clarifying agent, and to impart astringency, particularly to wines which have been diluted. The alumina may be estimated as follows (Louvet, Chem. Zentr. 1881, 252): 200 c.c. of wine are evaporated to dryness, the residue incinerated, and the ash fused in a platinum crucible with 3 grms. sodium carbonate, whereby the lime, magnesia, and ferric oxide are converted into insoluble carbonates. The mass is dissolved in water, and the solution filtered. As the solution may contain sodium aluminate, it is acidified with hydrochloric acid, treated with a large excess of sodium carbonate, and the alumina collected on a tared filter. The insoluble portion of the fused mass, containing the chief portion of the alumina, is fused with a few grams of pure soda, and the fused product digested with water and the solution treated for alumina as above described. The precipitates are collected, thoroughly washed, dried, ignited, and weighed. If any considerable proportion of phosphate is present, the phosphoric acid should be estimated and deducted from the total weight, the difference being Al_2O_3 .

Adulteration of wine.—Of the various processes already described which, strictly speaking, might be considered as 'adulteration,' some, as fortifying with spirit, sweetening with sugar, glucose, or glycerol and 'plastering,' are defended as legitimate trade practices of long standing or are officially tolerated within certain limits. Others, as dilution with water, the addition of antiseptics, astringents, colouring matters, and mineral acids, and of potassium hydrogen tartrate and cinnathic ether to give the fictitious character of age, have, as a rule, no other object than that of fraud.

In addition, wine is mixed with the juice of fruit other than the grape, and spurious wines containing no grape-juice whatever are made to simulate well-known types, as port, sherry, claret, and burgundy. The fruit basis of these is usually apple juice (v. p. 480), the other principal ingredients employed being crushed raisins, alcohol, sugar, tartar, flavouring essences, and colouring matters derived generally from the juice of such fruits as bilberry, elderberry, black currant, etc.

For the detection of dilution with water, fortifying with spirit, the addition of acids, tartar, glycerol, sugar, and other forms of sophistication of wines, reliance is placed in France and Germany upon the ratios which the respective principal constituents of the genuine wines of those countries bear to each other (e.g. in France, alcohol : extract (reduced) :

maxima and minima are adopted for the constants of genuine wines; but it does not necessarily follow that these can be accepted as standards applicable to the wines made in other countries and by different methods of manufacture. Whenever possible the suspected wine should be compared with a similar wine from the same district and vintage and known to be genuine. A concise and clear *résumé* of these constants and ratios will be found in Allen's Commercial Organic Analysis, 1924, vol. i. 242-7; see also Thudichum and Dupré's Treatise on the Origin, Nature, and Varieties of Wine; Windisch's Die chemische Untersuchung und Beurtheilung des Weines; Villiers et Collin, Traité des alterations et falsifications des substances alimentaires; Leach's Food Inspection and Analysis; and Post and Neumann's Traité complet d'analyse chimique appliquée aux essais industriels. WINE GUM v. GUMS.

WINTER GREEN, OIL OF, v. OILS, ESSENTIAL, and SALICYLIC ACID

WITGATBOOM. The dried root of *Boschia Transvaalensis*, Pest., *B. rehmanni*; *Marrua pedunculata*, Sim.; and *Capparis albitrunca*, Burch. Used as a substitute for chicory in certain parts of South Africa. For the microscopic and analytical characters of the roots and their aqueous extracts, see McCrae and Klooh, Analyst, 1918, 373.

WITHANIA SOMNIFERA, a plant found in South Africa, on the west coast of India, and along the shores of the Mediterranean. The root contains an essential oil, a quantity of sugar yielding *d* phenyl-glucosazone (m.p. 210°); a black resin from which the following substances have been isolated: hentriacontane $C_{31}H_{64}$; a phytosterol $C_{27}H_{46}O$ (m.p. 135°-136°); palmitic, stearic, cerotic, oleic, and linolic acids; ipuranol $C_{22}H_{42}O_2(OH)_2$; a monohydric alcohol, *withanol*, $C_{22}H_{42}O_4.OH$, decomposing at 305°, and having $[\alpha]_D + 91.2^\circ$, and an amorphous alkaloidal principle, which, on treatment with alkalis, yielded a crystalline base, $C_{17}H_{19}N_3$ (m.p. 116°).

The leaves and stems contain, in addition, a monohydric alcohol, *somnirol*, $C_{22}H_{42}O_4.OH$, decomposing at 205°, and having $[\alpha]_D + 34.8^\circ$; a dihydric alcohol, *somnitol*, $C_{22}H_{44}O_4(OH)_2$, decomposing at about 250°, and having $[\alpha]_D + 21.2^\circ$; and an acidic hydrolytic product, *withanic acid*, $C_{22}H_{42}O_5.CO_2H$ (m.p. 226°), the methyl ester of which decomposed at 255° (Power and Salway, Chem. Soc. Trans. 1911, 99, 490). These authors were unable to confirm the sedative and hypnotic properties attributed to this plant.

WITHERITE. Native barium carbonate ($BaCO_3$) crystallising in the orthorhombic system and isomorphous with aragonite and cerussite. The crystals are, however, invariably twinned, giving rise to pseudo-hexagonal forms; these may be either lenticular or pyramidal in habit, and in the latter case the six-sided pyramids present a certain degree of resemblance to crystals of quartz. Globular aggregates and compact fibrous masses also occur. The colour is white or grey; sp. gr. 4.3; H. 3½. The mineral occurs in some abundance in the lead-bearing veins traversing limestones, &c., at several places in the north of England and

on the borders of Shropshire and Montgomeryshire. It has been formed, in some instances at least, by the action of carbonated waters on barytes (L. J. Spencer, *Min. Mag.* 1910, 15, 310); and it is itself sometimes altered to barytes, as shown by the pseudomorphs of barytes after witherite. The best known locality, which has yielded many finely crystallised specimens, is the Fallowfield mine near Hexham; whilst the largest quantity (about 8000 tons per annum) is produced by the Settling-stones mine also in Northumberland. The mineral is also known from a few foreign localities, but only in small amounts.

Witherite is used in the manufacture of plate glass and porcelain, and for the preparation of barium dioxide (used in the manufacture of hydrogen peroxide), barium hydroxide (for refining beet-sugar), and barium salts (used, e.g. for giving the green light of fireworks). The mineral is also used for the preparation of the finer quality of barium sulphate ('blanc-fixé') used for facing glazed papers. The addition of a small proportion of witherite to clay (1 oz. per cwt.) in brick making prevents any efflorescence and discoloration due to soluble sulphates. Although insoluble in water, it is poisonous, since it is readily acted upon by the gastric juice; and the powdered mineral, mixed with meal, is used as rat poison.

References.—Special Reports on the Mineral Resources of Great Britain, *Mem. Geol. Survey*, 2nd ed. 1916, vol. ii; Barium Minerals (1913-1919), Imperial Mineral Resources Bureau, London, 1921. L. J. S.

WITT'S RULE *v.* COLOUR AND CHEMICAL CONSTITUTION.

WOAD (*Vouède*, *Pastel*, Fr.; *Waid*, Ger.). This commercial product is a dark clay-like preparation made from the leaves of the woad-plant, *Isatis tinctoria* (Linn.), an erect, herbaceous, biennial plant, belonging to the *Cruciferae*, bearing yellow flowers, small flat elliptical pods, and large smooth lanceolate or spatulate leaves.

The term 'woad' is derived from the Saxon 'wad,' which it has been suggested is derived from Woden, the Saxon God of War. It is synonymous with the Gallic *glastum*, with which, according to Pliny, the ancient Britons dyed their skin blue, in time of war and in connection with certain religious observances.

The plant is a native of Southern Europe, and from very early times has been employed in dyeing blue, for which purpose, previous to the introduction of indigo from India, it was largely cultivated in various parts of Europe—e.g. Thuringia, Languedoc, Piedmont, &c. Its cultivation has now declined almost to the vanishing-point.

In this country woad is now only grown, to a very small extent, in the fen lands of Lincolnshire and Huntingdon. The seed is sown in the early spring, March or April, and the young plants having been duly thinned and weeded, the leaves are ready for the first plucking in June, which, at intervals of five or six weeks, is repeated once or twice, or as often as fresh leaves shoot up.

The newly-gathered leaves are at once crushed or ground in edge-runner mills to a pulp, which is then placed in small heaps, to

drain, till sufficiently dry to cohere and be submitted to the 'balling' process. This consists in working the pasty mass by hand into balls, 4-6 ins. in diameter. These are at once spread out on wicker-work trays or 'fleaks,' and thoroughly dried in well-ventilated sheds. The balls are stored in a dry airy place till the whole crop has been gathered, and are then submitted to the so-called 'couching'—i.e. a fermentation—process. For this purpose the balls are ground to a coarse powder, which is spread on the floor of the couching-house to a depth of 2 or 3 feet, and there reduced again to the consistency of a paste by frequent sprinkling with water and turning over with shovels. During this process, which lasts from twenty to forty days, the mass becomes heated, and abundant offensive odours are given off. The operation needs to be conducted with some care and skill, so that the fermentation is neither so slow that a 'heavy' product is obtained, nor so rapid as to give one which is 'foxy.' When the fermentation has subsided, and the stiff, pasty mass is sufficiently cooled, it is packed in casks ready for the market.

It has been calculated that 9 parts by weight of woad leaves yield one part of the prepared product.

Although woad was formerly used for the indigo contained in it, it is at present only employed for the purpose of exciting fermentation in the indigo-vat ordinarily used by the woollen dyer, which is therefore termed the 'woad-vat.'

According to Wendelstadt and Binz (*Ber.* 1906, 39, 1627) woad contains two distinct micro-organisms, one of which under suitable conditions appears to be able to reduce indigo.

Spurious woad was sometimes prepared from the leaves of the rhubarb, cabbage, &c., but these products were very inferior to the true woad.

The colouring principle of woad leaves, considered by Schunck to be identical with that present in the *Indigofera*, is now known to be a distinct substance. This has not been isolated in a pure condition, but in its general reactions resembles indoxyllic acid (*see* INDIGO, NATURAL).

WÖHLERITE. Silicate, zirconate, columbate, and fluoride of calcium and sodium with the approximate formula $\text{Ca}_{10}\text{Na}_2\text{Si}_{10}\text{Zr}_2\text{Cb}_2\text{F}_{10}\text{O}_{11}$, and containing ZrO_2 15-23 p.c. The monoclinic crystals have the form of rectangular plates of a honey-yellow colour; sp.gr. 3.4; H. 6; decomposed by hot strong hydrochloric acid with separation of silica and columbic oxide. The mineral is usually regarded as a member of the pyroxene group. It occurs in nepheline-syenites in the Langesund-fjord in the south of Norway, in the Los Islands off the coast of French Guinea, and at Red Hill in New Hampshire; and in nepheline-phonolite in Haute-Loire, Auvergne. L. J. S.

WOLFRAM *v.* TUNGSTEN.

WOLFRAMINE *v.* TUNGSTITE.

WOLFRAMITE or **WOLFRAM.** A mineral.

consisting of iron and manganese tungstate ($(\text{Fe}, \text{Mn})\text{WO}_4$), crystallising in the monoclinic system. The name *ferberite* is applied to the members at the iron end of the series (FeWO_4), and *hübnerite* to those richest in manganese (MnWO_4). With this wide difference in composition the percentage of tungsten varies only slightly (WO_3 , 76.3–76.6 p.c.; analyses of the pure mineral show 74–77 p.c.). The mineral fuses readily before the blowpipe to a black, magnetic bead; and it is decomposed by *aqua regia*, with the separation of yellow tungstic oxide. Distinctly formed crystals are rare, but cleavage masses are of common occurrence. There is a perfect cleavage in one direction, parallel to the plane of symmetry. The mineral is opaque with a bright, sub-metallic lustre and a dark brown to black colour; the streak is dark reddish-brown to black; H. 5½. The high sp.gr. (7.2–7.5) and the lath-shaped cleavages are characters which assist in the identification of the mineral; while the latter character helps to distinguish it from other heavy black minerals. The name wolfram originated with the old German miners, and means, apparently, 'wolf froth,' since Agricola (1546) refers to the mineral as *lupi spuma*.

Wolframite usually occurs in veins traversing granitic rocks, and is often associated with tin ore. It is, in fact, obtained commercially mainly from tin mining districts; and formerly, before the mineral was of value, it was a source of trouble to the tin miner, since having about the same density as cassiterite it could not be separated from the ore by the ordinary mechanical methods. At one time it was eliminated in a soluble form by fusing the ore with soda (Oxland's process); but now it is extracted by the electromagnet (wolframite being weakly magnetic), and it forms a product as valuable as the tin ore itself. The principal wolfram-producing countries, arranged approximately in the order of their outputs, are: Lower Burma (at Tavoy), United States (Black Hills in South Dakota, Boulder and Gilpin counties in Colorado, Arizona, Nevada, &c.), Portugal, North Queensland (at Wolfram Camp, &c.), Bolivia, Peru, Argentina, Spain, England (Redruth, Bodmin Moor, and Gunnislake in Cornwall; Carrock Fell in Cumberland), France, Rhodesia, Siam, and New Zealand.

The mineral is used mainly for the manufacture of ferro-tungsten and the hard and tough tungsten-steel for tools and magnets of magnetos, and of some other alloys (e.g. 'partinum,' an alloy of tungsten and aluminium). Metallic tungsten is used as the filament of the so-called 'osram' electric lamps; as contacts for magnetos in place of platinum; and as a catalyser in the synthesis of ammonia. Wolframite is also used for the preparation of sodium tungstates and other salts.

WOLLASTONITE. Calcium metasilicate CaSiO_3 , crystallised in the monoclinic system, and belonging to the pyroxene group (*q.v.*) of rock-forming minerals. It differs, however, from the other members of this group in the directions of its cleavages, which are here along two planes perpendicular to the plane of symmetry and inclined to one another at $84^\circ 37'$. The mineral is white and opaque, sometimes with a pearly or silky lustre; sp.gr. 2.88–2.92; H. 5; decomposed by hydrochloric acid with separation of silica. It is a mineral of metamorphic origin, occurring in siliceous limestones that have been baked by intruded masses of igneous rocks. Bladed crystals are found in the limestone blocks ejected by Vesuvius, and large crystals, up to 10 inches in length and partly or wholly altered to quartz and opal, at the Santa Fé mine, in Chiapas, Mexico. Here, as is often the case elsewhere, the mineral is associated with bodies of metalliferous ores (H. F. Collins, *Min. Mag.*, 1903, 13, 356). The name wollastonite is after William Hyde Wollaston (1766–1828).

When heated, wollastonite changes at 1190° into the β -modification called pseudo-wollastonite (m.p. 1540°), which has been long known in slags and devitrified glasses under the name hexagonal calcium metasilicate. The latter has not been observed in nature, and the presumption is that wollastonite has been formed in contact-metamorphic limestones at a temperature below 1190° (E. T. Allen and W. P. White, *Amer. J. Sci.* 1906, 21, 89; 1909, 27, 1; A. L. Day and R. B. Sosman, *ibid.* 1911, 31, 341).

L. J. S.

WONGSKY, WONGSHY, WONGSCHY, HOANG TCHY. A Chinese yellow dyestuff. It consists of the fruit of the *Gardenia grandiflora*. According to Rochleder (J. 1858, 475), it contains *rubichloric acid* (see **MADDER**) and *crocin*, the glucoside of *Crocinin*, which is also present in saffron (*Crocus sativus* (Linn.)). Wongsky dyes aluminium and tin mordanted fabrics a yellow, whereas with iron mordant an olive colour is produced.

WOOD APPLE GUM v. GUMS.

WOODBURYTYPE v. PHOTOGRAPHY.

WOOD, DESTRUCTIVE DISTILLATION OF.¹ Wood completely freed from water has the following composition:—

Carbon, 50 p.c.
Hydrogen, 6 p.c.
Oxygen, 42.75 p.c.
Ash, 1.25 p.c.

¹ *W. Klar Technologie der Holzverkohlung*, 1912

The chemical nature of wood may be said to consist principally of cellulose, lignin, water, and of ash-forming materials.

The lignin in wood may be oxidised and removed by treatment with chlorine dioxide (Schmidt and Graumann, *J. Chem. Soc. Abstr.* 1921, [I.] 912; A. C. von Euler, *Cellulosechem.* 1923, 4, 109; *Chem. Soc. Abstr.* 1924, 126, [ii.] 129).

If wood is heated in a closed vessel with the air partly or entirely excluded and the vapours and gases are allowed to escape, the cellulose and lignin molecules are broken up by processes, the nature of which is little understood, but which are characterised by the formation of charcoal, which is left as a residue, and by the formation of gases and vapours, the latter of which, when condensed, is known as pyro-ligneous acid. P. Klason, Heidenstam and Norlin¹ concluded that the destructive distillation of wood may be represented by the following equation:—

They proved further that the destructive distillation of cellulose forms the most important products, viz. charcoal, acetic acid and tar; whilst lignin forms principally charcoal, acetic acid, wood alcohol and tar.

The destructive distillation of wood is occasionally carried out for the purpose of producing charcoal only, but at present it is more frequently the case that the by-products, acetic acid and the wood alcohol, are the most important substances yielded.

As regards the value of various kinds of wood for the process of destructive distillation, it has been shown that hard woods give the best yields of charcoal, acetic acid, and wood alcohol, whilst soft woods give smaller amounts of these products. Soft woods, however, show a larger yield than pine wood, which yields, besides the above-named products, a certain amount of turpentine, pine oils and pine tar oils. Local market conditions must decide in each case what is the most desirable wood for the purpose.

All wood for destructive distillation is split into cord-wood averaging 6 ins. in diameter and 4 ft. long. This initial preparation is usually carried out in the forest, but at manufactories recently erected in the United States large logs are brought to the saw mill where all the timber is utilised, and only those logs unfit for other purposes are used for cord wood. The cord wood is stacked in an exposed situation if possible, where it is allowed to dry and season for about 18 months, after which the moisture content will be found to be quite constant. The length of time required for this seasoning varies with the climate, and although it is thought that the moisture content of 20 p.c. is the most desirable, it is frequently found necessary to use wood containing 30 p.c. or more. A high percentage of moisture in the wood is undesirable owing to the fact that it delays the distilling process, decreases the

yields of acetic acid, wood alcohol and charcoal, whilst at the same time it increases the amount of noncondensable gases and also the amount of fuel used for the purpose of supplying heat for the distillation.

The process of destructive distillation is carried out in closed vessels built of brick or iron, and heated either by allowing the products of combustion to come directly in contact with the wood, excluding any excess of air; or by transmitting the heat through the walls of the vessel. In either case the distilling apparatus is connected with a condenser, the purpose of which is to condense the vapours formed during the reaction.

The apparatus for the destructive distillation of wood may be said to consist of three principal parts:—

- 1st. The container for the wood.
- 2nd. The arrangement for generating and supplying the heat to the container.
- 3rd. A condenser connected with the container by an intermediate vapour pipe.

After the wood has been placed in the distilling apparatus and the heating started, the water contained in the wood is first driven off; when this is accomplished the destructive distillation of the cellulose and lignin begins and will be indicated by the formation of non-condensable gases and by the appearance of the so-called pyro-ligneous acid, a brown liquor of characteristic odour, in which considerable tar is found. When the temperature reaches 270° an exothermic reaction sets in which supplies most of the heat necessary for the distillation process. The end of the process will be indicated by the cooling of the pipe which connects the distilling apparatus with the condenser.

In carrying out this distilling process on a commercial scale, the three phases of the distillation, namely: the expulsion of the water, the heating of the wood to the point at which the exothermic reaction sets in, and the completion of the process by means of the above-named reaction, will not necessarily take place consecutively, owing to the fact that the large-sized apparatus used will not allow the heat to be transmitted uniformly to all the wood in the vessel. Hence part of the wood situated near the heating surface may be in the third phase of the process, whilst that not so near the source of heat may be still in the first phase.

In general, yields of various products from air-dried hard wood in percentage by weight will be as follows:—

Charcoal, 25 to 27 p.c.

Crude pyro-ligneous acid, 45 to 50 p.c.

Gases, 25 to 28 p.c.

The composition of the charcoal will be variable, depending upon the process used and particularly upon the temperature at which the distillation has been finished. The following table gives the composition of charcoal produced by several processes:—

Process	P.c. O	P.c. H	P.c. O+N	P.c. ash	Tempe- rature
Old 'Meller' process	90.36	8.74	5.72	1.1	above 300°
Kilm process	84.18	5.22	11.72	0.78	400°
Retort process	81.15	4.24	13.64	0.78	500°

¹ Ark. Kenn. Min. u. Geol., 1908, Bd. 3, 2.

The *crude pyroligneous acid* will be found to be composed chiefly as follows:—

Water, 81 p.c.

Wood alcohol, 3 to 4 p.c.

Acetic acid, 6 to 8 p.c.

Dissolved and suspended tar, 7 p.c.

Other compounds contained, such as aldehydes, ketones, allyl alcohol, amines, phenols, and hydrocarbons are not of commercial importance and are of interest only in the refining of wood alcohol. The wood tar obtained from hard wood has little commercial value and is generally used as fuel. Small amounts, however, are used for the manufacture of creosote and wood tar pitch.

The *non-condensable gas* obtained by the destructive distillation of wood, amounting to 25–28 p.c. of the weight of the wood, varies in composition during the different phases of the process, and is composed on an average of carbon dioxide, 60 p.c.; carbon monoxide, 30 p.c.; hydrogen and hydrocarbons, 10 p.c. This gas is generally used for heating the retorts or boilers, and its heating value is equivalent to about 4–5 p.c. of the heating value of the wood decomposed in the process of distillation.

DESTRUCTIVE DISTILLATION OF PINE WOOD

The destructive distillation of pine wood containing rosin and turpentine, besides the cellulose and lignin, will produce products

different from those obtained from hard wood. The turpentine being volatile with water vapour is almost completely distilled over during the first phase of the distillation. In this phase, also, the rosin melting and flowing from the wood cells, covers the surface of the wood and the bottom of the distillation retort. During the second phase, this rosin will be decomposed, yielding such products as pinoline, rosin oils, and a residue of rosin coke. The pinoline will be mixed, more or less, with the turpentine originally contained in the wood, the rosin oils will combine with the tar formed in the usual course of wood distillation, and the rosin coke will be mixed with the charcoal. The mixture of turpentine and pinoline is known as crude wood turpentine. The presence of the rosin oils in the pine wood tar gives it a peculiar orange colour when painted on wood, which property makes it of considerable value. The amounts of acetic acid, wood alcohol and charcoal obtained from pine wood are considerably less than in the case of hard wood distillation.

An active demand for wood turpentine, for pine wood tar and pine wood tar oils, with good prices for these products and cheap prices for the wood, may cause, under certain circumstances, pine wood to be preferred to hard wood. But these conditions will not be frequent, and since the yields of acetic acid and wood alcohol and also of charcoal are considerably less, as the container can be filled with a larger weight

FIG. 1.

Brick wood-distilling apparatus for an 80-cord charge heated by burning a portion of the charge.

of hard wood than of pine wood (on account of the lower specific gravity of the latter), the efficiency of a distilling plant using hard wood is higher than one of the same size employing pine wood.

VARIOUS FORMS OF DISTILLING APPARATUS FOR CORD WOOD.

The number of forms of apparatus actually used for this purpose is large, and still larger is the number of designs which have been described in the literature or by patents taken out in different countries.

Only the most important types in practical use are given in what follows.

I. Distilling Apparatus made of Brick.

a. *Charring of the wood in brick kilns by fire gases which come directly in contact with the wood.*

1. *Fire gases generated inside the distilling apparatus by burning a part of the charge.*—To this type belongs the so-called 'American kiln,' seen in Fig. 1. This apparatus consists of a brick chamber, of about 15,000 cub. ft. capacity,

holding 80 cords of wood filled in by a top iron door *a*. There is a bottom iron door provided for discharging the charcoal. 4 ins. \times 4 ins. air inlet holes *d, d* are provided in the lower parts of the wall, and a couple of these kilns are connected by a brick goose neck *e* with the main smoke pipe, mostly built of wood. This main smoke pipe connects the kilns with the condenser plant *f g h*, and a fan is used for transporting the vapours and the gases from the kilns to the condensers and also for supplying the kilns with a certain amount of air, sufficient to generate the heat required for the destructive distillation of the wood by burning a certain amount of the wood, but avoiding any excess of air.

In the large plants at work in Michigan, often as many as 80 kilns are connected with condensers, using as much as 250 cords of wood per day, and condensing up to 50,000 gallons of crude pyroligneous acid. Unfortunately these kilns do not afford the proper amount of volatile by-products (acetic acid and wood alcohol) and about 50 p.c. of the possible yield is lost by being burnt to carbon dioxide and water. These kilns should only be used when wood is very

fuel and labour prices high and when there is not much demand for calcium acetate and wood alcohol. As these conditions seldom coexist, the kiln system must be considered wasteful and should be no longer used.

2. *Fire gases are generated outside of the distilling apparatus by fuel (mostly wood) in a special fireplace and conducted from there to the wood*—

2 represents such a type, originally known

FIG. 2

Brick wood-distilling apparatus according to Schwartz heated by a special open fire

as the 'Schwartz kiln'. The Swedish kilns of Ljungberg and of Ottelumska are of a similar type.

b. *Heating the wood in brick kilns by fire gas which, passed through radiators, transmits the heat by radiation to the wood*

Inside a brick chamber, cast iron or steel radiators are provided, through which fire gases are passed, which transmit the heat by radiation to the wood surrounding these radiators.

The oldest type of this kind of a wood distilling apparatus is represented by the 'Reichenbach kiln.'

Sweden developed a new form of this type called the 'Tube Oven,' seen in Fig. 3

These brick kilns do not permit the charcoal to be discharged immediately after the distillation is finished. In fact, every hok of the oven

FIG. 3

Brick wood-distilling apparatus heated by steel coil radiators

has to be closed by bricks so as to allow the charcoal to cool with absolute exclusion of air. This cooling process requires, in the case of large sized kilns (50 cords or more), as much as eight days, and the efficiency is decreased correspondingly. In order to discharge the charcoal from kilns heated by radiators, immediately after the close of the distillation, the wood must

be loaded on iron cars capable of being pulled or pushed into the brick container. After the distillation is finished the cars, loaded with hot charcoal, are pulled out quickly and transferred to a steel chamber of the shape of the brick container, when cooling will not require more than 24 to 48 hours. After the cars are withdrawn, other cars, already loaded with new wood and ready for charging, will be put into the brick chamber, still hot by the previous operation.

These brick kilns, heated by radiators, charged and discharged by iron cars, are the newest form of brick distilling apparatus.

A distilling apparatus built of brick is cheaper to build and possibly cheaper to maintain, but gives lower yields than steel apparatus as regards acetic acid and wood alcohol

FIG. 4

Vertical steel wood distilling apparatus for large charges, heated by fire gases circulating around the steel container, called 'Carboven', used in Sweden

on account of the difficulty of preventing the brick walls from leaking

II. Steel Distilling Apparatus.

A. Intermittently operated apparatus.

The most important representative of this type is the Swedish 'Carboven,' shown in Fig. 4. This apparatus can be loaded with 100 cords of wood, and will require about three weeks for filling, distilling, cooling and discharging.

A couple of inner vertical heating tubes, instead of one large one, is the characteristic feature of the homie steel distilling apparatus,

B. *Apparatus for discharging the charcoal immediately after the close of the distillation without cooling the charcoal before discharging.*

1. *Horizontal types*—a. *Apparatus for small charges.*—To these belong the distilling apparatus, generally called 'rotorts,' largely used in the past and still employed in Germany, Austria, Russia, Pennsylvania, and other countries or states. These rotorts are about 30 ins. in diameter by 10 ft. in length, are round in section, and contain $\frac{1}{2}$ cord wood. But they are also built for one cord capacity. Usually, one pair

WOOD, DESTRUCTIVE DISTILLATION OF.

These retorts is heated by the same fireplace, the products of combustion being conducted around the horizontally placed steel cylinders. One side of the retort is provided with a cast-iron door, the other tight end with a nozzle which serves to connect the retort with a condenser (see Fig. 5).

The wood is loaded by hand into these retorts. Inside the retort there is a semi-circular scraper, which is pushed to the rear before the retort is loaded and is provided with a rod with a handle ending near the door. After

the distillation is finished, a steel container is placed underneath the front of the door. The door is opened, and by means of the scraper the hot and burning charcoal is quickly emptied into the steel container, the cover of which is then closed air tight. A new charge is loaded immediately after discharging. While the new charge is distilling, the charcoal cools inside the container, which is built of thin sheet steel.

As one of these 39 ins. \times 10 ft. retorts can handle only $\frac{1}{2}$ cord of wood in 24 hours, this type of distilling apparatus is not well adapted for

FIG. 5

Horizontal steel retort for small charges; type, F. H. Meyer, Hanover-Hainholz.

the destructive distillation of wood on a large scale.

These small, horizontal retorts have the further disadvantage that the scraper used in discharging them causes much of the charcoal to be broken into small pieces. The charging of the retort by hand also requires many workmen, causing loss of time and decreasing the efficiency of the plant.

B. Wood distilling apparatus for large charges arranged for mechanically charging and discharging —The disadvantages above mentioned may

be avoided by employing retorts of large capacity, provided with mechanical contrivances for filling them with wood and also for discharging the charcoal. The distilling apparatus which meets these conditions best is the so called 'car retort.' A distilling apparatus of this kind consists of a horizontal steel retort, capable of working off a charge of 6 to 10 cords of wood (see Fig. 6). The wood is loaded on cars which are pulled or pushed into the retort; this has rails on the bottom and, according to its capacity, one or two doors for filling and

FIG. 6.

Horizontal steel retort, filled and discharged by cars; for charges up to 10 cords; type, F. H. Meyer, Hanover-Hainholz

discharging. Each car, made of steel, contains usually two cords of wood. The retort is connected by necks with one or two condensers of the usual tube type. The heating of these retorts is mainly effected by an open wood or coal fire and, to some extent, also by burning the tar and the gases obtained in the destructive distillation of the wood. The combustion gases travel by flues round the retort and escape in a smoke stack. The heating by an open fire has lately been replaced by producer-gas, obtained either in the usual way, that is generated by gas producers, or as a by-product in

the destructive distillation of the wood. A gas-heated retort will last longer, will use less fuel, and will yield higher results. The question of the best kind of gas producer for this purpose is dealt with later. After the distillation is finished the doors of the retort are opened and the cars, containing the hot charcoal, withdrawn and transferred as soon as possible to a horizontal steel cylinder, exactly corresponding in shape with the retort and also provided with doors for filling and discharging. The withdrawal of the cars is mostly done by means of a locomotive or by means of transportable electric

or steam hoists, and has to be done quickly in order to avoid the combustion of the charcoal. After the cars containing the hot charcoal are transferred to the horizontal steel cylinder, placed opposite the retort, the doors of the cylinder are closed air tight and the charcoal allowed to cool with exclusion of air. The cooling requires, according to the weather and character of the wood, from 24 to 40 hours.

This kind of wood-distilling apparatus further allows of the preliminary heating of the wood before filling it into the retort, by means of the waste combustion gases, which escape from the last retort flue into the smoke stack. In order to utilise this waste heat, the cars loaded with the wood are placed in a brick channel located opposite the charging door of the retort. The waste combustion gases are driven over the wood by means of a fan.

FIG. 7.

Vertical transportable retort; type, F. H. Meyer, Hanover-Hainholz.

Fig. 6 shows a modern distilling apparatus, having a higher efficiency than any other wood-distilling apparatus in practical operation.

A charge of 10 cords of wood is worked off in 24 hours, including filling, distilling and discharging, and it requires also very few workmen to attend to the firing, charging and discharging. By discharging the charcoal in a cold state and without the use of scrapers, a better class charcoal is obtained with the production of only a very small amount of powder or small pieces.

A revolving retort of a capacity corresponding to a charge of 6 to 10 cords of wood has been tried but discarded on account of the difficulty of contriving proper outlets and of keeping these outlets tight. Moreover, revolving retorts gave, of course, large amounts of charcoal powder and small charcoal.

2. *Vertical steel retorts.*—Vertical steel retorts, either built stationary or transportable, are in use in Germany, Belgium, France, Italy,

and also in Russia. France, in particular, is the country of vertical retorts, which are almost always constructed as transportable ones. These retorts contain a charge of 1 to 1½ cords of wood and are heated by an open fire or by a gas fire from underneath (see Fig. 7). They are filled outside of the settings, after being placed in a horizontal position. After the retort is loaded and closed it is lifted, by means of a travelling crane, above the open space in the settings to which the retort belongs. Then the retort is lowered into its place and its cover connected, by means of a copper goose-neck, with the condenser. After the distillation is finished, this copper goose-neck is taken off, the goose-neck hole in the cover closed, and then the whole retort is lifted out of the settings by means of the crane and transported outside of the building, placed in a horizontal position and then allowed to cool down, which will require from 12 to 24 hours, according to the charge and the weather. These retorts give good yields and afford good charcoal, but their efficiency is so good as that of the car retorts already described.

Sometimes these vertical retorts are constructed stationary and provided with a charcoal discharging door on the bottom. They are not as convenient as the transportable ones and do not give the same quality of charcoal, because the discharging is done by dumping, which causes breakages of the charcoal.

C. Continuously-working wood-distilling apparatus.

The distilling apparatus above described is either operated intermittently or only partly continuously.

But there are some types of distilling apparatus which are designed for continuous working as, for instance, the Swedish Groendal retort, which belongs to the type of the car retorts described on p. 493.

The Groendal retort consists of three main parts, namely:

1st. The drying chamber, built either of brick or of steel.

2nd. The distilling apparatus consisting of a horizontal steel retort.

3rd. The cooling apparatus for the charcoal, consisting of a steel cylinder of the shape of the retort.

These three parts are connected together but can be separated one from the other by means of vertical sliding doors of iron. The wood, loaded on cars, is filled in the drying chamber through which the exhaust combustion gases, escaping from the retort flues, are passed. After the drying is complete, the sliding doors between this drying chamber and the retort are lifted and the load transferred into the distilling zone of the system. This distilling apparatus is heated by any kind of heat generated by open fire or gas producers. The combustion gases travel around the steel shells, thus transmitting the heat to the wood inside the shell.

After the wood cars have passed the distilling part of the system, another slide door is opened and the cars with the finished charcoal are transferred into the charcoal cooling chamber, through which the cold non-condensable gases

escaping from the condensers of the wood-distilling apparatus, are passed in order to do the cooling work and preheat the gases. A double sliding door at the other end of the system allows the cooled cars with the cooled charcoal to be continuously passed out.

Another continuously working wood-distilling apparatus which may be mentioned here is the wood-gas producer, which, however, does not yield any charcoal. This wood-gas producer is used for the generating of heating gas from second-class cord wood or wood refuse in order to heat boilers and retorts, but also to recover, at the same time, the by-products of the destructive distillation of wood, viz. acetic acid and wood alcohol. These gas producers (Fig. 8) consist of a vertical brick or brick-lined steel furnace provided on the top with a funnel with double doors for filling the gas producer with wood while in work. The bottom of this

FIG. 8.

Wood-gas producers; type, F H Meyer, Hanover-Hainholz.

gas producer is provided with an iron grate through which a certain amount of air is allowed to enter. The upper part is connected with a condenser. In order to start the gas producers, charcoal has to be put upon the grate and allowed to become red hot. Then the filling in of the wood is started by means of the double-door funnel above-mentioned. The condenser, connected with this gas producer, communicates by means of a gas flue with the smoke stack of the boilers or the retorts, and by the natural draught of this smoke stack a certain amount of air enters through the grate into the gas producer, generating producer gas when coming in contact with the hot charcoal. This hot producer gas carbonises the wood on the top of the charcoal zone on its way up to the outlet, and forms, at the same time, the products of the destructive distillation. These escape, together with the producer gas obtained by passing air through the hot charcoal layer, into the condenser, and while the non-condensable gases escape by the main gas flue, the vapours of pyroigneous acid and of tar are condensed and discharged by means of a siphon. In such a gas producer, there will be a hot charcoal zone on

the bottom, above this there will be wood in the distilling state, and above this zone there will be another zone of wood in the drying period, and on the top of this drying zone there will be the zone of the green wood, filled through the funnel.

These gas producers are not very efficient; they yield no charcoal and only 50 p.c. of the amount of acetic acid and wood alcohol obtainable from the same amount of wood when distilled in retorts. But considering that they produce heating gas and at the same time allow 50 p.c. of the acetic acid and the wood alcohol to be recovered, they are important and economical in working under favourable conditions.

Apparatus for the destructive distillation of pine wood, rich in turpentine and rosin.—As already mentioned, some varieties of pine wood contain, besides cellulose and lignin, large quantities of rosin and turpentine.

As it is the purpose of the pine wood distillation to separate the turpentine in its original state as much as possible before the destructive distillation of the cellulose, lignin and rosin sets in, the apparatus for the destructive distillation of pine wood of this kind must be provided by a heating system which allows a uniform transmission of heat to any and every part of the wood contained in the retort, or which at least allows the temperature to be under control.

It has been proposed to heat the retorts for this purpose by electricity instead of by an open fire or by superheated air or gases circulating around the retort; by oil or metal bath contained in a double jacket; or by superheated steam brought directly in contact with the wood.

These proposals are still in the experimental stage, but it would seem that these methods of heating are too expensive, inasmuch as a carefully designed gas-heating system, using gas, producer gas, or natural gas, will do the same work more economically.

Any one of the apparatus already described may in general be employed for pine wood distillation. But for recovering the turpentine in its original state, or at least not very much contaminated with the products of the destructive distillation of the wood and rosin, the smaller units (6 cords capacity) of car retorts, heated by means of uniformly distributed gas burners, are most to be recommended.

DESTRUCTIVE DISTILLATION OF WASTE WOOD OR SPENT WOOD.

The splitting of the logs and cutting these into cord wood furnishes a large amount of small-sized wood waste. Also cutting the log into timber and working up the timber furnishes another class of waste wood known as slabs, edgings, shavings, sawdust, and so on.

As long as this wood waste consists of pieces large enough to furnish charcoal of the usual size, it can be handled just as cord wood in the standard retorts, and it will yield almost the same amount of charcoal, wood alcohol and calcium acetate as cord wood obtained from the same log, when these figures are referred to the weight and not to the volume of the wood, as a cord of slabs or edgings will weigh very much less than a cord of real cord wood.

With regard to the destructive distillation of

sawdust or shavings, this raw material is not capable of being distilled in any one of the standard apparatus previously described, on account of its voluminous character or by reason of the fact that there is not enough air space between the small, single wood pieces whereby the escape of the vapours and gases, formed on distillation, is rendered impossible. Back

pressure, and under unfavourable circumstances even an explosion, will be the consequence of trying to distil sawdust or other wood of this form in the standard wood distilling apparatus.

There have been numerous proposals to distil sawdust or other fine wood, and almost every one of these proposals is based either on the use of thin layers of sawdust or the use of stirring

FIG. 9.

Retort for distilling small wood waste

contrivances, or of a combined system of thin sawdust layers and stirring contrivances or scrapers, or finally on the briquetting of the sawdust before it is distilled.

None of these apparatus has taken a practical form, at least on a large scale up to the

price, for the large quantities of charcoal powder produced.

Figs 9 and 10 show types of apparatus which are used for this purpose. The apparatus (Fig 9) transfers the sawdust continuously by means of scrapers over fire heated steel plates, while in the apparatus in Fig. 10 the sawdust continuously drops down in thin layers by its own gravity between the space of the fire-heated shell of the vertical retort and the cast iron rings, which serve as outlets for the vapours and gases.

FIG. 10.

Vertical retort for the continuous distillation of small wood waste, type, F. H. Meyer

present time, neither small nor large plants which handle sawdust or a similar class of wood, are operated economically on account of the large initial outlay, which is out of proportion to the value of the output and on account of the fact that there is no market, at a sufficient

TREATING THE CRUDE PYROLIGNEOUS ACID.

Crude pyroligneous acid consists of a watery solution containing acetic acid, wood alcohol and its companions (aldehydes, ethers, ketones, allyl alcohol, phenols) and tarry matters in solution. This brown liquid is further mixed with tar in suspension.

Crude pyroligneous acid cannot be sold in large quantities, but acetate of lime and crude wood alcohol are in large demand.

The object of treating the crude pyroligneous acid is to separate the acetic acid and the wood alcohol from the water and the tarry materials.

First the tar, suspended in the liquid, is separated by allowing the liquor to stand. The tar will settle either on the top or on the bottom of the pyroligneous acid and is then drawn off.

But the remaining liquid still holds tar in solution and this dissolved tar must be separated in order to make marketable acetate of lime, which must contain at least 80 to 82 p.c. $(CH_3COO)_2Ca$.

There are several methods employed in order to separate the tarry matters in solution or suspension from the crude pyroligneous acid. The oldest process, still in use in some plants, consists in a simple redistillation of the crude pyroligneous acid in copper stills, connected

with a condenser and heated either by an open fire or better by a steam coil (Fig. 11). The tar remains as a residue. The distillate is a more or less water-white liquid, which is now practically free from tar and contains principally water, acetic acid, wood alcohol and its associated products above mentioned.

This method of removing the dissolved tar by simple distillation requires about 50 p.c.

FIG. 11.

Apparatus for distilling crude pyroligneous acid; type, F. H. Meyer.

the total amount of fuel or steam generated in a wood-distilling plant.

The author of this article introduced new methods of distillation of the crude pyroligneous acid, and up to date the crude pyroligneous acid of about 1000 cords of wood is so treated.

This process is based on the principle of the multiple effect evaporators, originally used in the manufacture of sugar (Fig. 12). Two or

FIG. 12.

Apparatus for continuous distillation of crude pyroligneous acid in multiple effect distillers; type, F. H. Meyer.

more distilling stills are used, one connected with the other and provided with contrivances to maintain a different but gradually lowered boiling-point or a different but gradually lowered working pressure in each one of the stills. For instance, still 1 will be heated by steam of 15 lbs. pressure, using a steam coil or any other heating contrivance.

The liquor, surrounding this steam-heated contrivance, is kept under atmospheric pressure. The pyroligneous acid vapours, generated in still 1 by means of the heating effect of the steam, enter the heating contrivance of the second still, kept under a lower pressure by means of vacuum and therefore a lower

boiling-point of the liquid than in still 1. Therefore the pyroligneous acid vapours, escaping from the first still, heat and distil the crude pyroligneous acid in the second still. This system can be continued indefinitely theoretically, but a system of four combined stills is all that can be reached practically.

A distilling apparatus of this type requires only one-third of the amount of steam or fuel hitherto used for distilling the crude pyroligneous acid in simple distilling apparatus; or the saving may amount to 100 p.c. when sufficient exhaust steam is available. Fig. 12 shows such an installation, based on the multiple effect distilling system.

Besides these two processes, used for redistilling the crude pyroligneous acid, there is another, employed more particularly in German plants.

This process combines the distillation of the crude pyroligneous acid with the neutralisation of the tar-free distillate by means of milk of lime or soda ash and the separation of the wood alcohol from the acetate solution.

The pyroligneous acid is distilled in a copper still, heated by a steam coil. Instead of passing the vapours of pyroligneous acid into a condenser, they are forced through milk of lime or soda ash solution, contained in closed copper or iron tanks, which are connected with a condenser (Fig. 13). The acetic acid thus combines with the lime or the soda, forming acetate solutions, whilst the wood alcohol and water vapours escape to the condenser from which an aqueous solution of the alcohol is discharged containing 5 to 12 p.c. wood spirit.

All the processes described above for removing tarry matters before treating the pyroligneous acid with milk of lime or soda ash solution, are based on the *distillation principle* and handle the gross distillate discharged from the condensers connected with the wood distilling apparatus.

The writer has introduced another patented process which is not based on the redistillation of crude pyroligneous acid, but depends on separating the total amount of tarry matters from the vapours escaping from the wood-distilling apparatus *before* these vapours are condensed. This is effected by washing the vapours and gases by means of crude wood tar or a mixture of crude wood tar and pyroligneous acid in two or more gas washing apparatus, which are combined together, and maintaining in each one a gradually decreasing temperature.

For instance, in the tar washer 1, a temperature of about 300°F. may be maintained and in the last tar washer, or the washer next the condenser, a temperature of 212°F. may be maintained.

By the combined effect of the fractional condensation of the tar and of the absorbing affinity of the large amounts of tar used as a washing liquid, for the small amounts of tar contained in the form of vapours in the products, the pyroligneous acid discharged from the condenser will be practically free from tar and ready to be neutralised by milk of lime or soda ash.

This process is successfully used in many wood-distilling plants and saves entirely the expenses of the redistillation of the crude liquor.

WOOD, DESTRUCTIVE DISTILLATION OF.

MANUFACTURE OF ACETATE OF LIME FROM CRUDE PYROLIGNEOUS ACID.

As already mentioned, grey acetate of lime, 80 to 82 p.c., is the product into which the acetic acid, contained in the pyroligneous acid, has to be transformed for the purposes of shipment.

The manufacture of grey acetate of lime starts with the tar-free distillate, obtained from the crude tar containing pyroligneous acid by one of the processes already described. This distillate is neutralised either by mixing it with milk of lime in a wooden tank, provided with a stirrer and cover, or by passing the vapours through layers of milk of lime.

The milk of lime combines with the acetic acid; it partly saponifies any methyl acetate; it transforms some of the aldehydes into insoluble resins; and it combines with phenols, forming insoluble lime compounds. After adding the milk of lime, the neutralised liquor is allowed to stand in order that the precipitates, formed by the neutralising processes, shall settle.

The next operation on the settled liquid, containing principally wood alcohol and its associates, acetate of lime and water, consists in separating the wood alcohol from the aqueous solution of the acetate of lime, either in form of a weak alcohol solution by means of a simple intermittently operated still, or in form of

FIG. 13.

Apparatus for distilling crude pyroligneous acid by passing acid vapours through layers of milk of lime; type, F. H. Meyer.

concentrated wood alcohol by means of an intermittently or continuously operated rectifier.

The simple distilling still furnishes a weak wood alcohol solution, containing from 8 to 10 p.c. of wood alcohol, whilst the rectifier turns out a single operation crude wood alcohol from 30 to 95 p.c., depending upon the design of the rectifier.

The simple still consists of a steel or copper still, provided with a copper heating coil and connected with a condenser.

The intermittently operated rectifier, shown in Fig. 14, is built of a steel or copper still with a copper heating coil, a copper column with rectifying sieve or bell plates, a separator and condenser. The working principle of these rectifiers is based on fractional distillation, and the 'columns' used for this purpose are very similar to those employed in manufacturing grain alcohol and known as the 'Savalle apparatus' from the name of the inventor. The

continuously working rectifiers, for separating the crude wood alcohol in a concentrated state from the neutralised liquor, are the most modern and most economically working apparatus for this purpose (Fig. 15). They have been introduced in the wood-distilling industry by the author of this article, and they furnish by a single operation the so-called 'crude wood alcohol' of 95 p.c. and separate at the same time the oils, originally contained in the neutralised liquor and also the acetone, if desired.

The continuously working apparatus are principally built of two columns; at the top of one column the neutralised liquor enters and the second column takes the wood-alcohol vapours escaping from the first column. The neutralised liquor travels in the first column downwards from plate to plate and meets on its way down the steam, entering into the bottom section. The wood alcohol, containing about 30 p.c. of wood alcohol and 70 p.c. of water,

WOOD, DESTRUCTIVE DISTILLATION OF.

escapes from the top section of the first column, while the acetate of lime solution freed from wood alcohol, is continuously discharged from the bottom section of this column. The 30 p.c. wood alcohol vapours enter the bottom part of second column, and on their way *upwards* from plate to plate they are concentrated by means of fractional distillation and discharged from

FIG. 14.

Intermittent-working rectifier for wood alcohol; type, F. H. Meyer.

the top section to a separator and from there to a final condenser, leaving the latter as a product containing up to 95 p.c. wood alcohol.

This product corresponds in chemical composition and physical characters with the so-called 'American Crude Wood Alcohol,' shipped in immense quantities from the United States to Europe. It still contains the total amount of acetone, aldehydes, ketones, esters, ammonia, amines, and allyl alcohol, originally contained in the neutralised liquor, and also some of the 'wood oils,' which always accompany the wood alcohol.

The average composition of this product may be given as follows:—

- 16 p.c. acetone and other ketones.
- 6 p.c. aldehydes, methyl acetate, and allyl alcohol and oils.
- 70 p.c. methyl alcohol.
- 8 p.c. water.

The following substances have also been found in 'wood spirit oil,' the residue left after the isolation of methyl alcohol from wood spirit: methyl ethyl ketone, methyl isopropyl ketone, dipropionyl-ethane, mesityl oxide, trimethyl acetic aldehyde, isovaleric aldehyde, Δ^4 -hexene-3-one, cyclopentanone (Fringsheim and Leibowitz, Ber. 1923, 56, [2] 2034; Chem. Soc. Abstr. 1923, 124, 1, 1062).

In order to manufacture 'pure' methyl alcohol from the crude wood alcohol, all these contaminating products have to be separated.

This is done by fractional distillation, carried out systematically by means of intermittently or continuously operated rectifiers, similar to those above described. The separation is usually assisted by adding chemicals—for instance, caustic soda and sulphuric acid—which destroy, polymerise, or saponify the products to be separated—for instance, aldehydes, esters, ketones, phenols, amines, and so on.

The separation of the acetone and the allyl alcohol, which are always associated with the methyl alcohol, is *entirely done* by a carefully repeated fractional distillation, which yields the concentrated acetone in form of 'head ends' and the allyl alcohol in form of 'tail ends.'

A mixture containing in specified proportion these head ends and tail ends represents the 'denaturing wood alcohol,' used practically everywhere for denaturing alcohol. This material must conform to certain specifications and tests prescribed by the different Governments.

The final product of such a repeated fractional

FIG. 15.

Continuous-working rectifier for wood alcohol; type, F. H. Meyer.

distillation, carried out either by intermittently working or continuously working rectifiers, represents the 'pure' methyl alcohol, which is free from acetone or contains only traces of it, and contains up to 99 p.c. real CH_3OH .

Besides this final product, free from acetone, and the 'denaturing wood alcohol' containing acetone, allyl alcohol, and other impurities, a

number of other wood alcohol grades are on the market; for instance, 'pure' methyl alcohol of 99½ p.c. with 0.1 to 1 p.c. of acetone and many other grades demanded by customers.

The pure grades are used for the manufacturing of aniline colours, of formaldehyde, of perfumes; the other grades for varnishes, as solvents, and the poorest grades for denaturing or burning.

The distillation of the neutralised liquor yields, as above shown, two products:

Wood alcohol, as a volatile product;

Acetate of lime solution as a non-volatile residue.

Fig. 16.

Open pan for evaporating acetate of lime solution.

This latter solution holds in suspension insoluble polymerised products, formed by a reaction between phenols and aldehydes with acetate of lime or traces of lime in excess, which must be settled by allowing the liquor to stand.

The settled solution contains varying quantities of acetate of lime, according to the nature of the original liquor and to the process used for distilling off the crude wood alcohol.

These quantities differ from 7 to 25 p.c.; this means, 100 lbs. acetate of lime solution may contain from 7 to 25 lbs. dry acetate of lime, 80–82 p.c. As it is impossible to recover the acetate of lime by a crystallising process on account of its equal solubility in cold and hot water, the solution must be boiled down until the salt is left in the solid state.

Up to the present this boiling was done in two steps. By the first step, the acetate of lime solution is evaporated in open, steam-heated, double-jacket pans (Fig. 16) just to the point at which the concentrated solution becomes solidified by crystallising. This point is reached when the acetate of lime solution contains about 35 to 40 p.c. of the dry salt. The crystallised magma is then spread out in thin layers upon an open drying floor, built of cast-iron plates or steel plates, heated by an open fire or by waste fire gases.

The operation of boiling down the acetate of lime solution to a magma of crystal requires very large amounts of steam on account of the coating of the heating surface by crystals and scales and by the immense reduction of the heat transmitting capacity.

Furthermore, the drying upon an open drying floor necessitates much hand work, as the material must be turned over and

usually transferred from one end of the drying floor to the opposite one, whereby it travels with the current of the fire gases. This ensures that the wet acetate of lime, which can stand a high temperature, comes in contact with the hot fire gases, while the dried salt or partly dried salt comes only in contact with the fire gases of a lower temperature, in order to protect it against decomposition into acetone.

The author has introduced a drying process, in which the solution of acetate of lime will be continuously and mechanically evaporated and dried, doing away entirely with the steam-heated open pans and the high wages required by opening drying floors.

By this new process, already in successful operation in plants of all sizes from 30 cords up to 250 cords, the acetate of lime solution is continuously evaporated in specially designed multiple effect evaporating apparatus, on the same principle as above described for the multiple green liquor distillers.

The weak solution enters the first evaporator, travels from there to the second, and from second to the third, leaving the same or the last one as a concentrated liquor, which contains up to 30 to 35 p.c. dry salt. This liquor will not crystallise when kept hot.

The liquor flows to a pan into which a rotary drum is dipping, heated inside by steam. This drum becomes coated with a thin layer of the concentrated solution.

While rotating, the thin layer dries quickly, and before the drum dips again into the concentrated solution the magma of crystals, which now coats the surface of the drum, is scraped off by means of knives, working on the surface of the drum (Fig. 17).

Fig. 17.

Continuous-working rotary evaporator for evaporating and drying acetate of lime; type, F. H. Meyer.

The magma of crystals then travels by means of a conveyor to a belt dryer, built of endless canvas belts or wire cloth belts, upon which the wet salt is transferred against a current of hot air or over pipe coils, heated by exhaust steam. This new type of apparatus for evaporating and drying acetate of lime does away with any kind of hand work; it obviates the disagreeable and unhealthy work of drying upon an open floor; and it saves almost all the wages hitherto spent for drying, and it saves, too, large amounts of fuel. Moreover, the acetate of lime obtained by this process, is of an even

form like peas; it does not contain much dust; it is of a brighter colour and is soft and voluminous, yielding on this account more acetic acid and acetone, when worked up into these products.

MANUFACTURE OF ACETATE OF SODA.

Next to acetate of lime, acetate of soda is the most important salt of acetic acid manufactured in wood-distilling factories.

In order to produce sodium acetate in a crystallised state, the distillate of pyroligneous acid, obtained by one of the processes already described, is neutralised by soda ash. The acetate of soda solution is then freed from wood alcohol by the methods before mentioned, and boiled down by open double-jacket pans, or by

modern multiple effect evaporating apparatus, until the crystallising point is reached. By the next step the condensed solution is completely dried in cast-iron, fire-heated pans, provided with scrapers, and the heating is continued until the whole of the water is driven off and the anhydrous sodium acetate is completely melted, when the liquid mass will have a temperature of about 320°. At this temperature, sodium acetate is not decomposed, but sodium propionate and butyrate, as well as tarry or resinous matters present in the original product, will be destroyed and converted into insoluble matters.

After melting, the mass is dissolved in water to form a concentrated solution and the charred matter separated by filtering the solution,

FIG. 18.

Cast-iron still for decomposing acetate of lime by sulphuric acid; type, F. H. Meyer, Hanover-Hainholz.

usually by a filter press. The filtrate is transferred to crystallising vessels and the crystals and mother liquor separated by a centrifugal machine. The crystals are recrystallised and the mother lees returned to the evaporating pans.

TREATING OF THE PRIMARY MARKETABLE PRODUCTS RESULTING FROM THE DESTRUCTIVE DISTILLATION OF WOOD.

The first products resulting from the destructive distillation of wood are: charcoal, crude pyroligneous acid, tar, when hard wood is distilled; or charcoal, crude pyroligneous acid, crude turpentine, crude pine oil and crude pine tar, when pine wood, containing turpentine and rosin, is employed. Of these, the charcoal only is ready for sale. The other products must be further treated in order to convert them into marketable commodities.

From the crude pyroligneous acid acetate of lime, acetate of soda and crude wood alcohol

are obtained, and from the latter the 'pure' methyl alcohol, the refined wood alcohol, and the denaturing alcohol as above described.

Many of the wood distilling factories work up the acetate of lime into acetic acid or acetone and the methyl alcohol into formaldehyde.

Manufacture of acetic acid.—In order to manufacture acetic acid, only acetate of lime, 80–82 p.c., is used nowadays as raw material. This is mixed with sulphuric acid of 92 to 98 p.c. in a closed cast-iron still, provided with stirrer and scrapers and heated by high-pressure steam (Fig. 18). After the mixing process is finished the acetic acid is distilled off, a vacuum being maintained in the still during the process of distilling. The crude acetic acid, resulting from the process, contains about 80 p.c. acetic acid (propionic and butyric acid included), traces of sulphur dioxide, and is of a yellow colour. This acid can be used for many purposes in the arts, as, for instance, manufacturing white lead, amyl acetate, &c.

In order to produce 'pure' glacial acetic acid of 96 to 99½ p.c., the crude 80 p.c. acetic acid, obtained by the action of sulphuric acid on acetate of lime, must be rectified in a copper rectifier (Fig. 19).

First a weak acetic acid is obtained containing propionic and butyric acid; then the distillate becomes gradually stronger and after distilling over 40 to 50 p.c. of the original charge, glacial acetic acid distills over: this has a melting-point of 14°-16° and contains 99 to 99½ p.c. CH_3COOH . At the end of the process the melting-point again falls, and with it the content of acetic acid owing to the presence of propionic and butyric acids.

In order to manufacture 'pure' acetic acid, 99½ p.c., corresponding to the requirements of the pharmacopoeas of different countries, the glacial acetic acid, obtained from the first rectification of the crude 80 p.c. acetic acid, will be oxidised and then redistilled by use of a simple still connected with a silver condenser.

Manufacture of acetone.—Acetone is manufactured by the dry or destructive distillation of

FIG. 19.

Apparatus for rectifying crude acetic acid in order to manufacture glacial acetic acid; type, F. H. Meyer.

calcium acetate. The process corresponds theoretically with the equation:

According to the author's patented process, used in most of the existing acetone factories, acetate of lime is spread out in thin layers on steel plates, to be placed one above the other upon platforms on steel cars, allowing sufficient

clearance from platform to platform (Fig. 20). These cars are pushed into horizontal steel retorts, heated by fire gases. The retorts are capable of treating from 3000 to 15,000 lbs. of

FIG. 20.

Retort for decomposing calcium acetate; type, F. H. Meyer.

calcium acetate in 24 hours and are conned with a condenser. The destructive distillation sets in at about 300°. After the charge is charred, the cars are withdrawn and other cars, already loaded, charged into the retort.

By the older acetone process, calcium acetate was distilled in charges not exceeding 1000 lbs. by means of fire-heated, closed, cast-iron pans, provided with a stirrer and scrapers. But these forms of apparatus yielded only 17 lbs. 'pure' acetone from 100 lbs. of calcium acetate instead of from 20 to 21 lbs. as obtained by the process above described.

There is a third process used, based on the distillation of calcium acetate by means of a stream of superheated steam which is brought directly in contact with the acetate.

The crude acetone obtained by one or other processes contains, besides the acetone, tarry matters, formic and acetic acids, aldehydes, ketones formed by the propionic acid and butyric acid originally contained in the crude material, hydrocarbons, and other products.

By means of repeated fractional distillation, assisted by the use of small amounts of caustic soda and sulphuric acid, acetone of 99½ p.c. is obtained, whilst the tarry matters remain in the residue. The acids are fixed by the alkalis, which destroy the aldehydes, and the foreign ketones and hydrocarbons are obtained as 'tail ends' from the rectifier, from the fact that their boiling-point is considerably higher than that of acetone.

FORMALDEHYDE.

This important disinfectant is obtained from the 'pure' methyl alcohol by oxidising it by the oxygen of the air under the influence of catalytic agents: $2\text{CH}_3\text{OH} + \text{O} = 2\text{CH}_2\text{O} + 2\text{H}_2\text{O}$. The manufacturing process differs in some respects from the theoretical equation, as side reactions set in whereby a part of this formaldehyde is broken up into carbon monoxide and hydrogen, according to the equation $\text{CH}_2\text{O} = \text{CO} + 2\text{H}$.

The excess of oxygen under the influence of the red hot catalytic material combines with the carbon monoxide as well as the hydrogen:

Carbon dioxide and water are products formed by another side reaction.

Theory indicates that 93.75 lbs. of formaldehyde of 100 p.c. should be obtained from 100 lbs. methyl alcohol of 100 p.c., but by the best practical process only 80 lbs. formaldehyde, as a maximum, can be obtained, which means only about 85 p.c. of the theoretical yield.

The product on the market is an aqueous solution of formaldehyde, containing from 35 to 40 p.c. CH_2O by weight. This solution is liable to polymerise, forming paraformaldehyde by the condensation of 3 mols. of CH_2O , a product which is not soluble in water and therefore causes the solution to become more or less turbid.

In order to avoid this polymerisation and to meet commercial demands, various substances are added to the formaldehyde solution. As methyl alcohol has the peculiar property of preventing polymerisation, a certain amount is added to the formaldehyde solution of the market, which averages

35-40 p.c. (by weight) CH_2O	
12-15 p.c. $\text{CH}_3\cdot\text{OH}$	
53-45 p.c. H_2O	

This solution is manufactured by mixing vapours of methyl alcohol with a corresponding amount of air.

The processes adopted for manufacturing formaldehyde differ in regard to the apparatus or contrivances used for furnishing this vapour mixture of a constant composition.

About half the factories existing at present are using the author's process, which is a continuous one, whereby liquid methyl alcohol is introduced in the form of a spray into the top section of a so-called 'carburator' (constructed on the same principle as that used for carbureting coal gas with benzene) and at the same time blowing a stream of hot air which enters the bottom of the 'carburator' against the methyl alcohol spray, whereby the methyl alcohol will be evaporated and mixed with the air in the right proportion. The mixture of methyl alcohol vapour and air is passed over the catalytic material, consisting of rolls of copper wire-net heated to about 400° , before allowing the mixture of methyl alcohol and air to enter.

To avoid explosions and to prevent the methyl alcohol burning into carbon dioxide and water, an excess of methyl alcohol must be used.

The products of the reaction, that is the vapours escaping from the apparatus, contain this excess of methyl alcohol, which is recovered by a fractional condensation of the escaping vapours, whereby the formaldehyde solution will be condensed first and the methyl alcohol last.

As already mentioned, the whole process is a continuous one, as methyl alcohol and air enter at one end of the apparatus, and the formaldehyde solution, the excess of the methyl alcohol used, and the nitrogen with the gases formed by the reactions will be discharged, of course each one separately, on the other end of the apparatus (v. FORMALDEHYDE).

CRUDE HARD-WOOD TAR.

The hard-wood distilling process yields two kinds of tar, namely: the settled tar, deposited

from the crude pyroligneous acid; the residue tar, obtained as a residue by distilling the crude pyroligneous acid.

The composition of these two varieties of tar is quite different, as the 'residue tar' contains principally pitch and pyroligneous acid, whilst the 'settled tar' contains, besides pitch and pyroligneous acid, the total amount of phenols and hydrocarbons, usually called 'tar oils.'

There are no two samples, taken from different plants, which are alike, and therefore exact figures concerning the composition of tar, obtained by the destructive distillation of wood, cannot be given.

Wood-tar is a burden on the hands of the wood distillers, on account of the difficulties it causes in the treatment of the pyroligneous acid, and on account of its small value as a commercial article.

The coal tar industry furnishes pitch and tar oils much cheaper and in much greater quantities than can be obtained from wood tar. The treatment of tar has therefore no great importance for the wood distiller, and usually it is limited to the recovery of the wood alcohol and acetic acid, the remaining tar compounds being, for the most part, used as fuel.

In order to recover methyl alcohol and pyroligneous acid, contained in both varieties of tar, the tar is subjected to distillation in copper stills, provided with a heating coil and also a perforated coil for adding live steam.

The water with the acetic acid, as well as with the wood alcohol, and light wood oils floating on water, is distilled, and when by increased steam supply the amount of distillate diminishes, live steam is added by the perforated coil and the distillation continued until the distillate contains only a small amount of acids. The distillate is allowed to stand, whereby the light oils rise to the top. The clear liquid is drawn off and treated together with the distillate obtained from the bulk of the crude pyroligneous acid.

The residue of this tar distillation, or that obtained by distilling off the pyroligneous acid from the tar, is a liquid similar to thick molasses, and is generally used as fuel which is burned by spraying it by means of steam into the fireplaces of boilers or retorts. Sometimes the settled tar is subjected to distillation in order to recover the heavy tar oils, containing the phenols and creosote and to manufacture pitch. Such distillation must be carried out in cast-iron stills, heated by an open fire. First the light oils, floating on water, and the pyroligneous acid distil over, as in the process described above. This phase of the distillation must be done very carefully on account of the frothing to which the tar is liable. After this period is over and when only small amounts of water flow from the condenser, the fire can be increased, when heavy tar oils, sinking in water, distil over. The distillation will be continued until the pitch, left as a residue in the still, proves to have the melting-point desired.

Sometimes hard pitch with a high melting-point, sometimes soft pitch with a low melting-point is the purpose of this distillation.

The heavy tar oils or the oil which sinks in water are usually sold to chemical works,

which manufacture creosote, and only exceptionally are they sold for the manufacture of dyes. Only a very few factories deal with the recovery of creosote, which contained up to 1 p.c. in the hard wood tar, particularly in beech tar.

The raw material is the 'heavy tar oil' obtained by the distillation of the settled tar in fire-heated stills. These oils still contain considerable amounts of tar and must be redistilled before being subjected to any other treatment. The redistilled oils are then subjected to a systematic extraction by means of caustic soda solution, which separates the total amount of phenols from the bulk of hydrocarbons contained in the tar oils.

The alkaline solution of phenols is then mixed with acid, usually a mineral acid, liberating the phenols, which are drawn off from the salt solution, after allowing the mixture to stand. Repeated fractional distillation is the next operation to which these mixtures of phenols are subjected in order to concentrate the fractions which contain the real creosote. These fractions are again subjected to repeated treatment with caustic soda and mineral acid, and from the last fractions of the distilled creosote, 'pure' creosote is obtained.

Crude turpentine and crude pine tar.—As described above, the destructive distillation of pine wood, rich in turpentine and rosin, yields the turpentine, partly in the state as originally contained in the wood, partly contaminated or mixed with the products of the destructive distillation of cellulose, lignin and rosin, i.e. with tar, tar oils, rosin oils, &c. The more nearly the distilling apparatus allows of a uniform distribution of heat to each piece of wood contained in the retort, the better will be the separation of the real turpentine, uncontaminated with the products above mentioned.

The destructive distillation of pine wood containing turpentine and rosin, yields three fractions, which are usually taken separately:

Fraction 1, containing only small amounts of tar, tar oils and rosin oils.

Fraction 2, containing less than 50 p.c. of the contaminating products.

Fraction 3, containing more than 50 p.c. of the contaminating products.

Fraction 1 represents the material, called 'crude wood turpentine,' which is exported from Sweden and Russia, and which is also manufactured in many factories situated in the Southern States of America, as Georgia, Alabama, Virginia, &c.

The 'crude wood turpentine' obtained by destructive distillation consists principally of terpenes. In addition it contains tar, acids, phenol, aldehydes, furfural, 'silvan,' dimethyl-furfural, benzene, toluene, xylene, diacetyl, acetyl-propionyl, &c.

The first treatment consists in fractionally distilling the crude wood turpentine by means of steam-heated stills, which allows also of the addition of live steam (Fig. 21), whereby the turpentine is separated from the products of lower and higher boiling-point. After the products of lower boiling-point have been got rid of, live steam is turned on and the mixture of vapours of turpentine and water is passed through caustic soda solution or milk of lime

in a container connected with the still and the condenser.

Phenols, rosin oil, aldehydes, acids, &c., are kept back or destroyed by the alkaline bath, whilst the turpentine and water vapours escape to the condenser and are separated after their condensation by their varying specific gravity.

The refined turpentine obtained by this process is of a water-white colour, but its smell is not 'sweet' enough to meet the requirements of the market.

It is therefore subjected to a second alkaline treatment and then to a treatment with sulphuric acid, whereby other contaminating products will be separated or destroyed.

Finally a fractional vacuum distillation by means of steam-heated rectifiers yields a duct, which is now of a water-white colour, of a 'sweet' smell, and has the same boiling point, specific gravity, and optical characteristics as ordinary turpentine.

'Pine wood tar' is obtained as the residue of the first distillation of the crude wood turpentine.

FIG. 21.

Distilling apparatus for separating turpentine from pine-wood tar-oils and pine-wood tar; type, F. H. Meyer.

The second fraction of the destructive distillation of pine wood, containing up to 50 p.c. tar and rosin oils, is also subjected to distillation as above described. The distillate is a mixture of turpentine, other terpenes and hydrocarbons of a higher boiling-point, called 'pine oil,' and the residue consists of pine tar.

The mixture of turpentine and pine oil is then subjected to fractional distillation by means of a vacuum rectifier and the turpentine obtained by this treatment mixed and treated together with the refined turpentine obtained from the first fraction.

The third crude fraction, mainly consisting of tar, is subjected to similar treatment and furnishes pine oils and, as a residue, the bulk of pine tar. M. K.

WOOD GUM v. GUMS.

WOOD OIL v. GURGUM v. OLEO-RESINS.

WOOD-OPAL v. OPAL.

WOOD-PITCH, WOOD-SPIRIT, WOOD-TAR, v. WOOD, DESTRUCTIVE DISTILLATION OF.

WOOD'S ALLOY v. TIN.

WOOD-TAR. According to Marcumson and Picard (Chem. Umschau, 1921, 28, 257), the composition of beech-wood tar and pine-wood tar is respectively as follows: unsaponifiable matter, 10.18 p.c., 53.5 p.c.; hydroxy-acid anhydrides, 9.5 p.c., nil; hydroxy acids,

52.3 p.c., 14 p.c.; resin acids, 7.7 p.c., 17 p.c.; fatty acids, 3.2 p.c., 6 p.c.; phenols, 9.3 p.c., 9.5 p.c. The residues (pitches) obtained after distilling these tars are composed respectively of: neutral tar resins, 14 p.c., 1.5 p.c.; unsaponifiable matter, 6 p.c., 19.7 p.c.; phenols, 1.5 p.c., 8 p.c.; hydroxy-acids and anhydrides, 7.7 p.c., 31.8 p.c.; resin acids, nil, 35.2 p.c.; fatty acids, 1.5 p.c., 2.8 p.c.; mineral matter, nil, 1 p.c.

Wood-tar pitches can be distinguished from other artificial asphalts by the high content of hydroxy-acids and the presence of phenols (J. Soc. Chem. Ind. 1921, 840 A.).

WOOD-TIN v. CASSITERITE.

WOODY NIGHTSHADE v. DULCAMARA.

WOOL. The woolly covering of the sheep is composed of modified hairs which grow in the same manner as the hairs of other animals, but differ from them considerably in physical structure and characteristics, including fineness, softness, waviness, and highly serrated surface. The wool fibre arises in the dermis or middle layer of the skin. Its root or follicle is a gland which produces a lymph-like secretion which nourishes the hair during its development and growth. This gland also secretes an oily substance, the wool-oil, which becomes a constituent part of the fibre and improves its elasticity and flexibility. Contiguous to the follicle are the sebaceous glands which secrete a fatty substance, the wool-grease, which coats the surface of the fibres, thereby protecting them from mechanical injury during growth and preventing them from becoming matted or felted together.

The dried perspiration of the animal also adheres to the fibres and can be removed by means of cold water in which it is soluble. It consists largely of a mixture of potassium salts, and is usually recovered as a by-product of the industry. The residue obtained after treating the wool with cold water and evaporating the solution to dryness is known as 'sudorate of potash.' Raw wool yields about 8 p.c. of this product.

Before the wool can be used for the manufacture of textiles, not only must the dried perspiration be removed, but also the wool-grease; the extraction of the latter is generally effected by the process of scouring with soap and water. In order to avoid the removal of the wool-oil from the interior of the fibre, the temperature at which the scouring is carried out does not usually exceed 50°.

When examined with the microscope, the typical wool fibre presents the appearance of a more or less cylindrical rod covered with irregularly-shaped scales which overlap one another by their free margins and cause the fibre to exhibit numerous serrations. The free edges of the scales always point in the direction of growth of the fibre. It is to this peculiar imbricated nature of the surface that the felting property of wool is due. The shrinking which wool fabrics undergo on washing is also attributable to the serrations; the rubbing of the material causes the projecting edges of the scales to become closely interlocked, and thus reduces the amount of space occupied by the fibres, and this behaviour is facilitated by the lubricating action of the soap. The cortical layer beneath the scales constitutes the bulk of the fibre and is

composed of long, narrow cells with pointed ends. Within this is the medulla which consists of larger and rounded cells and often contains pigment to which certain wools owe their characteristic colour. In the finer wools, the medulla is often so much reduced as to be almost indistinguishable. The wool of carelessly-bred sheep frequently contains defective fibres in which the scales and cellular structure are but slightly developed; these appear as stiff, straight, coarse, opaque hairs which cannot be dyed, and are termed 'kemps.'

The value of wools and their suitability for different purposes depend very largely on their physical properties, such as length, strength, elasticity, fineness, softness, curliness or waviness, lustre, felting property, colour, and freedom from impurities and kemps. The extent to which a wool possesses these characters varies greatly with the particular breed of sheep, the climatic conditions, the nature of the pasturage, and the care exercised in selection and rearing. The quality of the fibre also varies considerably in different parts of the same fleece. The wools of commerce may be roughly divided into three classes: (1) long-stapled, (2) medium-stapled, and (3) short-stapled.

(1) The long-stapled class includes the typical English varieties, such as the Lincoln, Leicester, and Cotswold wools. The fibre is from 6 to 10 ins., or even up to 15 ins. in length, has an average diameter of about 0.001 in., and bears from 600 to 1400 serrations per inch. It is nearly white, lustrous, of good elasticity, and has a smoother surface and less wavy character than the fibres of the other classes. The scales are horny and closely attached to the cortical layer and, in consequence, the felting power is poor. These wools are specially adapted for the manufacture of worsted yarns.

(2) The medium-stapled class is represented by the wools produced by the Southdown sheep and those of the Cheviot Hills, Shropshire, Hampshire, Oxfordshire, and Dorset; it also includes certain cross-bred wools, such as those of Australia, New Zealand, and South America, which are produced in very large quantities. The characters of the fibre are intermediate between those of the long- and short-stapled kinds. The length is from 3 to 8 ins., the average diameter about 0.0008 in., and the average number of serrations is about 2000 per inch.

(3) The short-stapled class comprises the finest grades of wool, including those of the merino type of Australia, South America, and the Cape Province of South Africa. The fibre is from 2 to 5 ins. long, has an average diameter of about 0.0005 in., and bears about 2800 serrations per inch. It is either white or of a greyish tint, has little or no lustre, and is very elastic, very soft, and curly. The scales are small and adhere to the cortical layer by only a small portion of their length, so that the upper part is free and protruding, and for this reason the wool has good felting properties. Wools of this class are particularly suitable for the manufacture of woollen fabrics.

Wool fibre is composed of a protein substance of the group known as the keratins, which also includes those derived from hair, horn, whale-bone, feathers, and egg-membrane. All the

members of this class differ from other proteins in yielding a large proportion of cystine on hydrolysis. The average elementary composition of wool keratin is approximately as follows: C, 51; H, 7; O, 21; N, 17; S, 4 p.c.

Sulphur is the most variable constituent and ranges from 2.5 to 4.5 p.c. Raikow (Chem. Zeit. 1905, 29, 900) found that when wool is kept for some time in contact with syrupy phosphoric acid, sulphur dioxide is evolved. Baudisch (*ibid.* 1908, 32, 620) confirmed this result and also showed that the sulphur of wool is partly oxidised to sulphur trioxide by the action of hydrogen peroxide. The experiments indicate that some of the sulphur is in direct combination with oxygen and is probably present in the form of a sulphite-like complex. This conclusion, however, has been challenged by Strunk and Priess (Zeitsch. physiol. Chem. 1912, 76, 136).

Schützenberger (Compt. rend. 1878, 86, 767) investigated the decomposition of wool keratin by solution of barium hydroxide at 170°, and found that 100 grms. of purified wool yielded nitrogen (evolved as ammonia), 5.25 grms.; carbon dioxide, 4.27 grms.; oxalic acid, 5.72 grms.; acetic acid, 3.2 grms.; pyrrole and volatile products, 1-1.5 grm.; whilst the residue consisted of leucine, tyrosine, and other nitrogenous substances.

The hydrolysis of wool keratin by hydrochloric acid was studied by Abderhalden and Voitnovici (Zeitsch. physiol. Chem. 1907, 52, 348), and it was found that various amino acids were produced in the following quantities p.c.: glycine, 0.6; alanine, 4.4; valine, 2.8; leucine, 11.5; tyrosine, 2.9; serine, 0.1; cystine, 7.3; proline, 4.4; aspartic acid, 2.3; and glutamic acid, 12.9. A comparison of these results with those obtained by the hydrolysis of the keratins of hair, horn, and feathers showed that all these substances are different, and led to the conclusion that keratin is a mixture of proteins.

Purified wool contains 1-2 p.c. of mineral constituents. The following analyses of the ash of a sample of Lincoln wool are due to Bowman. The wool, after being scoured, washed, and dried, yielded 1 p.c. of ash, of which 75 p.c. was soluble in water.

	Whole ash	Soluble ash	Insoluble ash

100.0 100.0 100.0

Scoured wool usually contains about 13-14 p.c. of water. The fibre is hygroscopic and the amount of moisture present therefore varies a good deal with the state of the atmosphere. On this account, it is the custom for the moisture in a consignment of wool to be estimated before sale, and the true selling weight calculated on a certain standard percentage of moisture, the

so-called 'regain.' The standard adopted at Bradford and Manchester for scoured wools is 16 p.c. of the weight of the dried fibre.

Determinations of the moisture-absorbing capacity of different kinds of wool in the various forms met with in industry have been made by Shorter and Hall (J. Text. Inst. 1924, 15, 305; J. Soc. Chem. Ind. 1924, 43, B. 628).

Wool is very susceptible to attack by dilute alkali hydroxide and is easily dissolved by a boiling 5 p.c. solution of sodium hydroxide. This reaction is employed for estimating the amount of wool in a material composed of a mixture of this fibre and cotton. When, however, wool is treated at the ordinary temperature with a strong solution of sodium hydroxide (sp.gr. 1.4-1.5), the fibre is not destroyed, but becomes white and lustrous, acquires a 'scoop' (the grating sound caused by rubbing the fibre) resembling that of silk, shows a greater affinity for dyestuffs, and increases in strength to an extent of about 30 p.c. Wool treated in this manner is said to be 'mercerised.' The process results in the removal of a large proportion of the sulphur; Matthews found that a sample of wool, originally containing 3.42 p.c. of sulphur, retained only 0.53 p.c. after being mercerised.

Strong solutions of potassium and sodium carbonate at high temperatures cause the disintegration of the fibre; but weak solutions at moderate temperatures are not injurious, and are extensively used in the scouring process.

By boiling purified wool with solution of barium hydroxide, removing the excess of the reagent with carbon dioxide, and adding solution of lead nitrate, a precipitate is produced which on treatment with hydrogen sulphide yields a product termed 'lanugine acid' (Champion, Compt. rend. 1871, 72, 330). This substance has been re-examined by Knecht (J. Soc. Dyers, 1889, 71), who describes it as a brownish-yellow solid which dissolves slowly in cold water and easily in hot water. Its aqueous solution precipitates acid and basic colouring matters with formation of coloured lakes. Knecht found the substance to have the following composition: C-41.61; H-7.31; N-10.26; S-3.35; O-31.44.

Wool is completely destroyed by strong mineral acids, but is little affected by dilute acids. When heated with dilute nitric acid, the fibre assumes a permanent yellow colour. If it is warmed with dilute sulphuric or hydrochloric acid, it becomes harsher to the touch and acquires an increased affinity for dyes. The resistance of wool to the action of sulphuric acid enables it to be quantitatively estimated in a fabric composed of a mixture of wool and cotton or other vegetable fibre. The fabric is steeped for some hours in a mixture of equal volumes of concentrated sulphuric acid and water, with the result that the vegetable fibre is destroyed, whilst the wool is not attacked and can be collected, washed, dried, and weighed.

Nitrous acid seems to diazotise the amino groups of wool keratin. Wool which has been treated with this reagent is harsh to the touch, non-hygroscopic, and assumes various colours when brought into contact with alkaline solutions of certain phenols.

Kann (Färber-Zeit. 1914, 25, 73) has found that small quantities of formaldehyde render

wool less sensitive to alkali although this does not affect its behaviour towards nitrous acid. He therefore concludes that the wool molecule does not contain amino- and keto-groups but imino- and carboxy-groups.

Wool is very little affected by dry chlorine, but is decomposed by the gas in presence of moisture. The fibre is capable of absorbing chlorine from weak solutions and becomes harsh, acquires a 'scroop,' loses its felting properties, thus becoming 'unshrinkable,' and also acquires an increased affinity for colouring matters.

For further information, reference should be made to Bowman's Structure of the Wool Fibre, or to Matthews' Textile Fibres. E. G.

WOOL BLACK, v. AZO-COLOURING MATTERS.

WOOL FAT consists of a mixture of the esters of cholesterol and of alcohols of the fatty series, including ceryl alcohol and alcohols with a smaller number of carbon atoms. Isocholesterol and carnaubyl alcohol would appear to be absent. The fatty acids are cerotic, palmitic, stearic acids, and hydroxystearic acid (?), together with resin acids, and lanoceric anhydride (Röbmann, Biochem. Zeitsch. 1916, 77, 298). It melts at about 30° to 40°, and is characterised by the readiness with which it absorbs water.

According to Lifschutz, the fat from the surface wool of the sheep contains a larger proportion of fatty acids and soaps than that near the roots. The latter contains isocholesterol, while the surface fat contains oxycholesterol (Zeitsch. physiol. Chem. 1924, 241, 146).

WOOL OILS. The trade term 'wool oils' or 'cloth oils' comprises all those oils used by woollen manufacturers for lubricating the wool before spinning, or for oiling the rags before 'grinding' and 'pulling.'

The best wool oils consist of pure fatty oils, such as olive oil, lard oil, neat's foot oil. Besides these, oleic acid ('saponification oleine' or 'saponified oleine,' 'distillation oleine' or 'distilled oleine' (see SAPONIFICATION)) is used largely as a cheaper kind of wool oil.

Cheap wool oils, for use with the lowest textile goods, include 'distilled grease oleine,' and even 'waste oils,' such as 'black recovered oil,' 'seck oil,' and 'brown grease oil'; which contain considerable amounts of unsaponifiable matter. Besides these oils there are found in commerce large quantities of 'manufactured oils,' representing blends of the above-named wool oils, as also blends containing mineral oils. For the detection of hexaline in textile oils, see Marcusson (Chem. Zeit. 1924, 49, 656), and for general methods of examination, see Lewkowitsch, Chem. Techn. J. L.

WOOL SCARLET v. AZO-COLOURING MATTERS.

WOOTZ. An Indian name for steel.

WORMSEED v. SANTONICA.

WORMSEED, OIL OF, v. OILS, ESSENTIAL.

WORMWOOD. The leaves and tops of *Artemisia Absinthium* (Linn.) contain a volatile oil, *absinthol* (q.v.), and a bitter principle, *absinthin* (q.v.). Wormwood is a bitter stomachic tonic, and is used in medicine as a remedy for atonic dyspepsia, and as an anthelmintic.

WORT v. BREWING.

WOURALI, WOURARA, WOURARI v. CURARA.

WRIGHTINE v. CONESSINE.

WULFENITE (*Gelbbleierz*, *Molybdänbleispat*, Ger.). A mineral consisting of lead molybdate $PbMoO_4$ crystallising in the tetragonal system (hemimorphic-tetrahedral class) and isomorphous with scheelite (q.v.). Next to molybdenite (q.v.) it is the most abundant of the few minerals containing molybdenum. It has been found in some quantity at Bleiberg in Carinthia, and at several places in Arizona, Nevada, Utah, Mexico, Spain, and Morocco, often as beautifully crystallised specimens of rich yellow or red colours.

L. J. S.

WURTZILITE. A mineral hydrocarbon, found in Utah and elsewhere, and used in the manufacture of varnishes, roofing compositions, &c.

WURTZITE. A native form of zinc sulphide (ZnS) crystallising in the hexagonal system, and thus dimorphous with the more common cubic mineral zinc-blende (q.v.). It was described from Oruro in Bolivia by C. Friedel, and named after the French chemist C. A. Wurtz (1817-1884). Crystals are hemimorphic and very like those of zincite (ZnO , q.v.); but, as a rule, the mineral forms fibrous masses. Much fibrous and shelly blende which is optically birefringent, and known by the names 'spiauterite' and 'Schalenblende,' really belongs to this species; and it sometimes, no doubt, forms an important part of massive zinc sulphide ore. The colour is brownish-black with resinous lustre, and the streak is brown; sp.gr. 3.98 (for artificial crystals 4.087); H. 3½-4. The phosphorescence shown by the mineral when struck has often been observed by miners.

The hexagonal zinc sulphide used for coating phosphorescing screens in Röntgen-ray work is the artificially prepared material. This was first obtained by J. Durocher in 1851, by E. H. Sainte-Claire Deville and L. Troost in 1861, and more successfully by T. Sidot in 1866 (Compt. rend. 62, 999; 63, 186). Sidot obtained long, colourless and transparent, hexagonal prisms by subliming blende in a current of sulphur dioxide. On the artificial production and stability relation of the two modifications of zinc sulphide, v. E. T. Allen and others (Amer. J. Sci. 1912, 34, 341; 1914, 38, 412).

L. J. S.

X

XAMETRIN. Syn. for hexamethylenetetramine.

XANTHALINE v. OPIUM.

XANTHEIN. The name applied by Fremy and Cloez to the soluble yellow colouring matter of flowers.

XANTHENE COLOURING MATTERS.

XANTHENE COLOURING MATTERS, a name sometimes applied to the dyestuffs con-

taining the group $\begin{array}{c} \diagup \text{O} \diagdown \\ | \\ \diagdown \text{O} \diagup \end{array}$ and including the *pyro-*

nine colouring matters and triphenylmethane colouring matters (*q.v.*).

XANTHIC ACIDS (*Alkylordithiocarbonic acids*) $\text{RO}\cdot\text{CS}\cdot\text{SH}$, may be prepared by dissolving sodium in the required pure dry alcohol and adding the calculated quantity of dry carbon disulphide, the mixture being stirred and cooled. In this way a sodium xanthate is formed, which, on treatment with dilute sulphuric or hydrochloric acid, yields the free xanthic acid (Ragg. Chem. Zeit. 1908, 32, 630, 654, 677; *ibid.* 1910, 34, 82).

Xanthic acid (*Ethylhydrogen dithiocarbonate*) is a colourless, transparent, heavy oil, insoluble in water and quickly decomposing into alcohol and carbon disulphide, due to autocatalysis, the alcohol, formed as a product of the decomposition, being the catalyst. If the xanthic acid is mixed with phosphoric acid it becomes more stable and can be kept for weeks (*see* von Halban and Kersch, Zeitsch. physikal. Chem. 1913, 82, 325; Zeitsch. Elektrochem. 1918, 24, 65, who have studied the kinetics of its decomposition). It forms a large number of metallic salts. The sodium or potassium salts when treated with a copper salt yield *cuprous xanthate* and *ethylthioxythiocarbonate* (*dixanthogen*) thus:

The cuprous salt is yellow, and it is this reaction which led to the adoption of the name for these salts. When the metallic xanthates are heated to 350° they decompose with evolution of hydrogen sulphide, carbon dioxide, and small quantities of combustible gases containing carbon monoxide. Amongst the liquid products are carbon di- and oxy-sulphide, ethyl hydrogen sulphide, ethyl mono- and disulphide, and ethyl alcohol, but in the case of the silver and nickel salts, the liquid product consists of almost pure ethyl xanthate and the dry distillation of the nickel salt is recommended for the preparation of the ethyl salt (Hébert, Compt. rend. 1911, 152, 869).

Potassium propylxanthate has been proposed as a reagent for cobalt and nickel salts; with the latter it yields a yellow precipitate, whilst with the former a green precipitate is formed. In dilute solutions the nickel is precipitated before the cobalt. *Potassium methyl xanthate* is also a good reagent giving with nickel a soluble, with cobalt an insoluble, salt in ammonia (Ferrer Hernández and Campo y Cedán, Anal. Fis. Quim. 1911, 9, 173). *Cf.* Whitby and Beardwood (J. Chem. Met. Soc. S. Africa, 1921, 21, 199), who employ potassium or sodium xanthate for the separation of nickel and cobalt.

Arsenic xanthate $\text{As}(\text{S}\cdot\text{CS}\cdot\text{OEt})_3$, m.p. 94.8° (corr.), prepared by the action of potassium xanthate (3 mols.) on a solution of any compound of arsenic (1 atom), is absolutely insoluble in hot or cold water, or cold acetic acid, readily soluble in benzene, carbon disulphide, carbon tetrachloride or chloroform. The formation of

this compound may be employed as a quantitative method for the determination of small quantities of carbon disulphide (Tarugi and Sorbini, Chem. Zentr. 1912, ii, 1398).

Molybdenum xanthate $\text{Mo}(\text{S}\cdot\text{CS}\cdot\text{OEt})_3$, m.p. 108° (decomp.), is prepared when CS_2 is treated with alcoholic KOH and then with ammonium molybdate and dilute sulphuric acid. Cadmium xanthate can be prepared in like manner (Cecchetti. Gazz. Chim. Ital. 1925, 55, 104; Chem. Soc. Abstr. 1925, i, 503). Alkyl- and aryl-mercuric hydroxides react with CS_2 and an alcohol forming alkyl- and aryl-mercuric xanthates such as $\text{MeHg}\cdot\text{S}\cdot\text{CS}\cdot\text{OEt}$ and $\text{C}_6\text{H}_5\text{Hg}\cdot\text{S}\cdot\text{CS}\cdot\text{OMe}$ (Koten and Adams, J. Amer. Chem. Soc. 1924, 46, 2764; Chem. Soc. Abstr. 1925, i, 236).

When sodium or potassium alkyl xanthate is treated with chloracetyl carbamides, the following products are obtained: chloracetyl carbamates, arylamines, xanthylacetyl carbamides, ethyl carbamates, and arylamides (Freilichs and Rentschler, Arch. Pharm. 1906, 244, 77).

The esters of xanthic acid and its homologues may be obtained by treating the alkali salts with alkyl halide. They are volatile liquids which react with alkali alkoxides thus:

(Salomon, Ber. 1875, 8, 1507; Wallach, *ibid.* 1880, 13, 530).

When treated with ammonia they yield mercaptan and *xanthamides* (alkylthiocarbamates) $\text{RO}\cdot\text{CS}\cdot\text{NH}_2$. The *ethyl salt*

which is known as *xanthamide*, has m.p. $40^\circ\text{--}41^\circ$ (Debus, Annalen, 1850, 75, 128; *ibid.* 1852, 82, 262; Salomon, J. pr. Chem. 1874, [ii.] 8, 115; Rosenheim and Stadler, Zeitsch. anorg. Chem. 1906, 49, 1). Mixed xanthic anhydrides have been prepared (Richter, Ber. 1916, 49, 1026).

Xanthic derivatives of certain carbohydrates, such as starch, have been prepared by first saturating the dry powdered carbohydrate with carbon disulphide and then adding the required quantity of caustic soda solution (Fr. Pat. 370505, 1906; J. Soc. Chem. Ind. 1907, 267). For other literature, *see* Tschugaceff, Ber. 1900, 33, 735; Bull. Soc. chim. 1901, [iii.] 26, 184, 298, 502; Leuckart, J. pr. Chem. 1890, [ii.] 41, 179; Holmberg, *ibid.* 1905, [ii.] 71, 264; Billmann, Annalen, 1906, 348, 133; Friedländer and Lenk, Ber. 1912, 45, 2083; Billmann and Madson, 8th Inter. Cong. App. Chem. 1912, 25, 339; Ramberg, Ber. 1913, 46, 1696; Dubsky, J. pr. Chem. 1914, [ii.] 90, 61; Holmberg, Zeitsch. physikal. Chem. 1914, 88, 385; Dubsky, J. pr. Chem. 1916, [iii.] 92, 142; Ferrer, Anal. Fis. Quim. 1918, 16, 724; Delépine and Compin, Bull. Soc. Chim. 1920, [iv.] 27, 469.

XANTHINE. 2:6-dioxypyrimine

was discovered in 1817 by Marcet in a urinary calculus and called 'xanthic oxide,' because of the yellow residue it left when evaporated to

dryness with nitric acid. Wöhler and Liebig analysed the compound, which they isolated from another calculus, and found that it differed from uric acid in containing one atom of oxygen less in the molecule (Annalen, 1838, 26, 340). It occurs in guano (Strecker, *ibid.* 1861, 118, 157), to a small extent in urine, 10,000 litres contain 10.11 grms. (Krüger and Salomon, Zeitsch. physiol. Chem. 1898, 24, 371; 26, 367); in the muscles, liver, spleen, pancreas, thymus and brain (Micko, Zeitsch. Nahr. Genussm. 1903, 6, 781; 1904, 7, 257). It is also found in the actively growing tissues of plants, in yeast, tea, and seedlings of lupins and malt; and has been isolated, together with other purine bases, from the soil (Schreiner and Shorey, J. Biol. Chem. 1910, 8, 385). According to de Waele (Chem. Zentr. 1913, 11, 519, from Zeitsch. Imm. expt. Therapie, 1913, 18, 11, 410) xanthine is an intermediary product in poisoning by nucleoproteins.

Synthesis.—Xanthine can be prepared by heating 2:6:8-trichloropurine with sodium ethoxide, and reducing the 2:6-diethoxy-8-chloropurine either directly by hydrogen iodide,

or after preliminary hydrolysis, to 2:6-dioxy-8-chloropurine (Fischer, Ber. 1897, 30, 2232).

Xanthine is also obtained by heating 2:6-di-iodopurine with hydrochloric acid under pressure (Fischer, *ibid.* 1898, 31, 2550). Traube (*ibid.* 1900, 33, 1371, 3043) has effected the synthesis of xanthine from cyanacetyl-urea; this is converted by the action of alkalis into 4-amino-2:6-dioxypyrimidine which, by the action of nitrous acid and subsequent reduction, yields 4:5-diamino-2:6-dioxypyrimidine: on heating the sodium salt of the formyl derivative of this compound, xanthine is obtained.

When uric acid is reduced by nascent formic acid, it yields xanthine. This may be effected by heating a mixture of uric acid, formic acid, chloroform, and alkali on the water bath: or by heating a mixture of equal weights of uric acid, calcium formate and calcium hydroxide in a combustion furnace until evolution of gas begins; or, more simply and with a yield of 30–33 p.c., by heating at 200° uric acid mixed with oxalic acid and excess of glycerol (Sundvik, Zeitsch. physiol. Chem. 1897, 23, 476; 1898, 26, 131; 1912, 76, 486; Skan. Arch. Physiol. 1911, 25, 256). Johns and Hogan (J. Biol. Chem. 1913, 14, 299) obtained xanthine by boiling hypoxanthine-2-thiolacetic acid with 20 p.c. hydrochloric acid.

The following technical preparation of xanthine from thioxanthine is described by C. F. Boehringer and Soehne, D.R.P.P. 141974, 142468, 143725. An alkaline solution of isouric acid absorbs sulphuretted hydrogen, forming a salt of γ -thio- ψ -uric acid, which is converted by boiling with mineral acids into thioxanthine (2:6-dioxy-8-thiopurine); or the thioxanthine may be prepared by warming 4:5-diamino-2:6-dihydroxypyrimidine with carbon disulphide and potassium hydroxide. On oxidising thioxanthine by means of nitrous acid, hydrogen dioxide in alkaline solution or manganese dioxide in neutral solution, it is converted into xanthine.

Xanthine is conveniently prepared from guanine by the action of nitrous acid, or, more readily and with a yield of 60–70 p.c. by heating it in a reflux apparatus for 32 hours with

25 p.c. hydrochloric acid (Fischer, Ber. 1910, 43, 805)

Properties.—Xanthine crystallises with one molecule of water which it loses at 125°–130°, forming a colourless micro-crystalline powder that acquires a waxy lustre by friction (Wöhler and Liebig, *l.c.*); it dissolves in 14,151 parts of water at 16° or 1300–1500 parts at 100°, and is insoluble in alcohol or ether. It dissolves readily in solutions of sodium or potassium hydroxides or in ammonia, but is precipitated from the solution by acids, even carbon dioxide. Xanthine sublimates slightly when heated, but decomposes without melting, yielding carbon dioxide, ammonia, hydrocyanic acid and cyanogen.

Xanthine is oxidised by chlorine oxides or chlorine water, yielding alloxan and urea (Fischer, Annalen, 1882, 215, 253).

Milk and certain animal tissues contain a *xanthine oxydase*, which is probably identical with Schardinger's enzyme and with Haas and Hill's 'atite' (Morgan, Stewart and Hopkins, Proc. Roy. Soc. 1922, [B], 94, 109; Haas and Hill, Bio-Chem. J. 1923, 17, 671; Dixon and Thurlow, *ibid.* 1924, 18, 971, 976, 989; 1925, 19, 507, 672; 1926, 20, 703).

Detection and estimation.—Xanthine gives the murexide reaction when evaporated to dryness with chlorine water or hydrochloric acid and potassium chlorate and the residue moistened with ammonia solution; this is commonly

called 'Weidel's test' for xanthine, although this author described it as a test for *hypoxanthine* (Annalen, 1871, 168, 365), and Kossel showed that the reaction was due to the presence of *xanthine*, pure *hypoxanthine* not responding to the test (Zeitsch. physiol. Chem. 1882, 6, 431).

Xanthine dissolves in hot nitric acid without evolution of gas, and the yellow residue obtained on cautious evaporation of the acid solution turns reddish-yellow on addition of sodium or potassium hydroxide and changes to reddish violet on heating. If ammonia be used instead of the alkali hydroxides, no violet colour is produced, and this test distinguishes xanthine from uric acid which gives the murexide reaction when similarly treated.

If dry xanthine be sprinkled on an alkaline solution of bleaching powder, each particle becomes surrounded with a dark green ring or scum which quickly changes to brown and finally disappears. Xanthine develops a red colour when added to an alkaline solution of diazobenzenesulphonic acid.

Xanthine can be estimated by precipitating the insoluble silver compound by means of silver nitrate from an ammoniacal solution, and estimating the nitrogen present in the carefully washed precipitate by the Kjeldahl method; or the silver may be estimated gravimetrically or volumetrically.

For the separation of xanthine from the purine bases in urine or extract of tissues, see Abderhalden's Handbuch der Biochemischen Arbeitsmethoden, vol. iii. part 2. p. 894. Also Thiéry (J. Pharm. Chim. 1921, 23, 494).

Salts and derivatives.—Xanthine forms compounds with certain metallic oxides and salts, the compound with *silver oxide*

is a flocculent precipitate obtained by precipitating an ammoniacal solution of xanthine with ammoniacal silver nitrate; with *silver nitrate* $C_5H_4O_2N_4 \cdot AgNO_3$ a flocculent precipitate prepared by mixing a nitric acid solution of xanthine with silver nitrate solution; the compound with *lead* $C_5H_4O_2N_4 \cdot Pb$ is white and crystalline; and the compound with *barium hydroxide* $C_5H_4O_2N_4 \cdot Ba(OH)_2$ is sparingly soluble. Xanthine forms crystalline salts with the mineral acids which are generally readily hydrolysed by solution in water; the *sulphate*

crystallises in pearly rhombic plates from hot strong sulphuric acid, or in microscopic needles from dilute acid; the *hydrochloride*

crystallises in warty masses; the *nitrate* $C_5H_4O_2N_4 \cdot HNO_3$ is precipitated as a heavy crystalline powder, when a warm solution of xanthine in sodium hydroxide is added to a cold solution of nitric acid (2:3); the *periodide* $C_5H_4O_2N_4 \cdot HI \cdot I_2$ forms characteristic green crystals from alcohol (Linarix, J. Pharm. Chim. 1909, [vi.] 30, 241). The phospho-tungstate crystallises in straw coloured cubical plates (Drummond, Bio-chem. J. 1918, 12, 5):

Xanthine-7-diazobenzenesulphonic acid

dark red crystalline needles that do not decom-

pose at 265°, soluble in water or alkalis, insoluble in ether, sparingly soluble in alcohol (Burian, Ber. 1904, 37, 703).

8-Chloroxanthine $C_5H_3ClO_2N_4$, obtained by hydrolysing 2:6-diethoxy-8-chloropurine with hydrochloric acid, forms a sparingly soluble crystalline powder which blackens without melting when heated (Fischer, Ber. 1887, 30, 2236).

8-Bromoxanthine $C_5H_3BrO_2N_4$, obtained by direct bromination at 100°, or by the action of nitrous acid on bromoguanine; is a crystalline powder, insoluble in cold, sparingly soluble in hot water, insoluble in alcohol or ether, and decomposes without melting (Fischer and Reese, Annalen, 1883, 221, 343).

8-Thioxanthine $C_5H_3(SH)O_2N_4$, obtained by heating 8-bromoxanthine with potassium hydrogen sulphide solution in a sealed tube at 120° (Fischer, Ber. 1898, 31, 433), or by methods already referred to in the description of the synthesis of xanthine: is a colourless heavy crystalline powder which blackens without melting on being heated, sparingly soluble in concentrated hydrochloric acid and readily soluble in alkalis.

obtained by the electrolytic reduction of xanthine dissolved in sulphuric acid, using lead electrodes; forms colourless crystals that decompose without melting after becoming brown at 250° (Tafel and Ach, Ber. 1901, 34, 1166). It is very readily hydrolysed when gently heated with acids, yielding carbon dioxide, ammonia and 5-aminomethyl-4-iminazolone

Tafel and Mayer, Ber. 1908, 41, 2546).

For *acyl* derivatives of xanthine series, compounds of the general formula

where X is xanthine or a mono- or dialkyl substituted xanthine and R is the radicle of an alcohol, phenol or amine, v. Merck (D. R. P. 290910; J. Soc. Chem. Ind. 1916, 35, 654); they combine the diuretic action of xanthine with the therapeutic properties of the phenol, etc.

For formaldehyde derivatives which are of therapeutic value, v. Bayer & Co., D. R. P. 54488; and for soluble derivatives, v. Bayer & Co., D. R. P. 264389. M. A. W.

XANTHINE (CHRYSANILINE) v. ACRIDINE YESTUFFS

XANTHOCROITE v. GREENOCRITE.

XANTHOCREATININE, CHRYSOCREATININE and AMPHICREATININE are the chief members of the creatinine leucomaines isolated by Gautier from the muscles of large animals; they are alkaloidal in properties, and when administered to animals act more or less powerfully on the nerve centres inducing sleep, and in some cases vomiting and purging in a manner similar to the alkaloids of snake poison. These bases are formed during life and occur in the urine, saliva, and various glandular secretions (J. Pharm. Chim. [v.] 13, 354, 401; Bull. Soc. chim. 48, 16).

Xanthocreatinine $C_8H_{10}ON_4$ is the most

abundant of the creatinine leucomaine group of bases. It was extracted from muscle by Gautier and also by Monari (Gazz. chim. ital. 1887, 16, 538) and from the urine of the lion by Colosanti (*ibid.* 21, ii. 188). In chemical properties it closely resembles creatinine from which it differs in empirical constitution by CH_2N . It crystallises in light sulphur-yellow spangles which have a slightly bitter taste and an odour, similar to that of crude acetamide. The base is soluble in cold water and can be crystallised from boiling alcohol. It is amphoteric in character, turning blue litmus red and red litmus blue. It forms a salt with hydrochloric acid which yields soluble crystalline double salts, with the chlorides of gold, platinum, mercury and zinc. The latter compound has the formula

Chrysocreatinine $\text{C}_8\text{H}_9\text{ON}_4$ crystallises in orange-yellow crystals, is feebly alkaline towards litmus paper and has a slightly bitter taste. It forms a crystalline non-deliquescent hydrochloride, which yields crystalline double salts with platinum, auric and zinc chlorides respectively.

Amphicreatinine $\text{C}_8\text{H}_9\text{O}_4\text{N}_7$ crystallises from boiling water in bright, pale yellow prisms and is less readily soluble than either of the two preceding bases. When heated at 110° the crystals become colourless and opaque without, however, changing their form. It forms a crystalline hydrochloride. The *platinochloride* is soluble in water, and insoluble in alcohol and crystallises in lozenge-shaped plates, and the *aurichloride* is very readily soluble and crystallises in microscopic hexahedral and tetrahedral crystals.

XANTHONE. Xanthone or diphenoylpyrone—

known also as *diphenylene ketone oxide*, *benzophenone oxide*, *carbodiphenylene oxide* $\text{C}_{13}\text{H}_8\text{O}_2$, was first prepared by Kolbe and Lautermann (Annalen, 1860, 115, 197), by the action of phosphorus oxychloride on sodium salicylate and has been subsequently obtained from salicylic acid and its derivatives by the employment of various dehydrating agents. The most convenient method consists in distilling a mixture of acetic anhydride and salicylic acid (W. H. Perkin, Chem. Soc. Trans. 1883, 43, 35; cf. also Graebe, Annalen, 254, 265), when the higher boiling fraction on cooling deposits crystals of xanthone. During the reaction some phenol is produced and is indeed found to some extent in the distillate, and the reaction though probably more complex, may be considered to consist of the condensation of phenol and salicylic acid with formation of the xanthone. See also Dhar (Chem. Soc. Trans. 1920, 117, 1055).

Phenyl salicylate (Siefert, J. f. prakt. Chem. [ii.] 31, 472) by long digestion at the boiling temperature yields xanthone, and it is also produced when salicylic acid phenyl ether

is warmed with sulphuric acid (Graebe, Ber. 21, 503). Other methods of this type have been described by Richter (J. f. prakt. Chem. [ii.] 28, 275), Jeiteles (Monatsh. 17, 66), Staedel (Annalen, 283, 179), Goldschmidt (Monatsh. 4, 123), and Klepl (J. f. prakt. Chem. [ii.] 28, 217). Fosse (Compt. rend. 1903, 136, 1006) has also obtained xanthenes by warming the phosphoric esters of phenols with potassium carbonate. For the theory of xanthone formation the paper of Strohbach (Ber. 1902, 34, 4136) should be consulted. Ullmann and Zlokasoff (*ibid.* 1905, 2111), by the interaction of sodium phenoxide and sodium *o*-chlorobenzoate in the presence of copper powder, obtained *o*-phenoxybenzoic acid (1) which by elimination of water passes into xanthone (2).

Xanthenes of the anthraquinone series can be prepared by the action of condensing agents on phenyl, naphthyl, or anthraquinonyl esters of 1-hydroxyanthraquinone 2-carboxylic acids (D. R. P. 251696).

Xanthone crystallises in long colourless needles, m.p. 173° – 174° and dissolves in sulphuric acid to form a blue fluorescent liquid. The oxonium salts *xanthone hydrobromide* $\text{C}_{13}\text{H}_8\text{O}_2\text{Br}$ and *xanthone stannichloride*

have been obtained by Gomberg and Cone (Annalen, 1910, 376, 183). By distillation with zinc-dust or by the action of fuming hydriodic acid at 160° , it is converted into *xanthene* (methylene diphenylene oxide) or diphenoylpyran—

which may also be regarded as the anhydride of 2,2'-dihydroxydiphenylmethane. By oxidation with chromic acid, xanthone can be reproduced (Merz and Weith, Ber. 14, 192). With boiling alcoholic soda and zinc-dust xanthone gives *xanthidrol* (Meyer and Paul, Ber. 1893, 26, 1276)—

and with zinc-dust and acetic acid *dioxo-xanthylene* (Gurgenganz and v. Kostanecki, Ber. 1895, 28, 2310) is produced—

Fusion with alkali gives *xanthonic acid*, dihydroxybenzophenone

and from this by means of dehydrating agents xanthone can again be reproduced. The disruption of the γ -pyrone ring in this manner by the action of hydrolytic agents is characteristic of compounds containing this and the γ -pyran nucleus. In the flavone group this hydrolysis takes place even more readily, and to this to some extent may no doubt be ascribed the lack of permanence of these colouring matters when applied to fabrics as compared with those of the anthraquinone group.

Interesting is the fact that when ketone colouring matters, and indeed all hydroxyketones, are alkylated in the usual manner with alkyl iodide and alcoholic potash, the hydroxyl in the ortho position to the carbonyl group remains unaffected, a fact which may be considered as an example of steric hindrance. This, at first pointed out by Herzig (Monatsh. 12, 161) in connection with the ethylation of euxanthone (dihydroxyxanthone) and quercetin, was observed by v. Kostanecki and Dreher (Ber. 1893, 26, 71) to be the property of all xanthenes containing hydroxyls in the position 1 or 8

and the non-reactivity of the hydroxyl in this position has served in many cases as an indication of the presence of a carbonyl group. Such partially methylated compounds are as a rule, insoluble in aqueous alkali, but give with alcoholic potash insoluble salts, which are readily hydrolysed with water. It has, however, been shown by Perkin in special instances that the alkylation of this hydroxyl group can be readily effected if a considerable excess of the reagents be employed, and it is probable that this method is of a general application (Chem. Soc. Trans. 1913, 103, 1632).

a-Dinitroxanthone, m.p. 190° (Richter, l.c.; Graebe, l.c.), *b*-dinitroxanthone, m.p. 262° (Perkin, Chem. Soc. Trans. 43, 189), *a*-diaminoxanthone, m.p. 209° (Graebe), *b*-diaminoxanthone (Perkin), xanthone disulphonic acid (Perkin), monobromoxanthone, m.p. 125°-127° (Graebe), dibromoxanthone, m.p. 212° (Perkin), xanthone phenylimine, m.p. 134°-135°, and xanthone oxime (Graebe and Röder, Ber. 32, 1689) have been directly prepared from xanthone.

3-Nitro-xanthone, m.p. 176°, 3-chloroxanthone, m.p. 171° (Ullmann and Wagner, Annalen, 1907, 356, 359), 3-aminoxanthone, m.p. 232°, 3-methoxyxanthone, m.p. 129°, 3-hydroxyxanthone, m.p. 243°, 1-hydroxyxanthone, m.p. 147° (Ullmann and Panchaud, *ibid.* 350, 108), 2,4-dinitroxanthone, m.p. 206° (Ullmann, *ibid.* 1909, 366, 79), 4-chloroxanthone, m.p. 130°, 4-bromoxanthone, m.p. 126° (Gomberg and Cone, *ibid.* 1909, 370, 142), xanthione, m.p. 156° (Graebe and Röder)—

and dithioxanthone—

have been obtained indirectly.

The following derivatives have also been prepared:—Ootochloroxanthone, m.p. 324° (Eckert and Steiner, Monatsh. 1915, 36, 175); 1-chloroxanthone, m.p. 100°; 2-chloroxanthone, m.p. 165°; dichloroxanthone, m.p. 225°; 2-bromoxanthone, m.p. 150°; tetrabromoxanthone, m.p. 298°; hexabromoxanthone, m.p. 308°; 1-nitrobromoxanthone, m.p. 210°; 2-nitroxanthone, m.p. 200°; 4-nitroxanthone, m.p. 127°; 2:3:7-trinitroxanthone, m.p. 205°; six isomeric tetranitroxanthenes, β -nitroaminoxanthone, m.p. 265°, giving an acetyl derivative, m.p. above 300°; α -nitroaminoxanthone, m.p. 204°-206°, giving an acetyl derivative, m.p. above 300°; dinitroaminoxanthone, m.p. with decomposition 205°-210°; α -dinitroxanthhydrol, m.p. 185°; β -dinitroxanthhydrol, m.p. 196°; nitroxanthoquinoline, m.p. 205°-210°; dibromodinitroxanthone, m.p. 235°-237°; tetrabromodinitroxanthone, m.p. 300°; 2-chlorotetranitroxanthone, m.p. 205°; 4-chlorotetranitroxanthone, m.p. 235°; 4-chlorodinitroxanthone, m.p. 195°-200°; dichlorodinitroxanthone, m.p. 240°; 2-bromo- α -tetranitroxanthone, m.p. 210°; 2-bromo- β -tetranitroxanthone, m.p. 212°; 1-anilinoxanthone, m.p. 120°-125°; dibromodinitroxanthone (C₁₂H₈O₂Br₂(NHPh)₂, m.p. 140°-145°; hexaanilinoxanthone, m.p. 180°-183°, phenyliminodinitroxanthone (C₁₂H₈O(NO)₂:NPh, m.p. 170°-175°; β -nitroxanthone-azo- β -naphthol, β -nitroxanthone-azo:1:5-dihydroxynaphthalene, α -nitroxanthone-azo-phenol, dinitroxanthone-azo- β -naphthol, m.p. 270° (Dhar, Chem. Soc. Trans. 1916, 109, 744; *ibid.* 1920, 117, 998, and 1053); 8-hydroxy-2:3-quinoxanthone and its derivatives (Dean and Nierenstein, Chem. Soc. Trans. 1920, 117, 802). Xanthone 4-carboxylic acid, m.p. 289°, its derivatives and salts (Anschütz and Cloasen, Ber. 1922, 55, [B] 680); 5:6:7-trichloro-2-methylxanthone 8-carboxylic acid (Ullmann and Schmidt, Ber. 1919, 52, [B] 2098); 2:3:4-trichloro-6-hydroxyxanthone 1-carboxylic acid, m.p. 279°-280°, and its salts (Orndorff and Adamson, J. Amer. Chem. Soc. 1918, 40, 1235); 3-bromo 2-methylxanthone, m.p. 146°; 3-bromo-xanthone 2-carboxylic acid, m.p. 338°-340°, its methyl ester, m.p. 154°-155°. Dixanthone

m.p. 353°, by heating 4:6-diphenoxyisophthalic acid with conc. H₂SO₄; 3-anilinoxanthone 2-carboxylic acid, m.p. 310°-313°, the acid chloride of which gives with AlCl₃ the acridone xanthone

2:5-diphenoxyterephthalic acid gives the dioxanthone

(Eckert and Seidel, J. pr. Chem. 1921, [ii] 102, 338); 1:4-dichloroxanthone, m.p. 159°-161°; 4-chloro-1-methoxyxanthone, m.p. 156-158°; 4-chloro-1-hydroxyxanthone, m.p. 156°; 4:4'-dichloro-1:1'-dixanthonyl, m.p. 290°, which on reduction gives the pinacone, m.p. 276°-278°

from this meso-benzdixanthylene, m.p. 236°-237°, dixanthonyl and mesonaphthidianthylene, m.p. 140°-150°

were obtained (Eckert and Endler, J. pr. Chem. 1922, [ii] 104, 91). 7-Chloro-2-methylxanthone 8-carboxylic acid, m.p. 286° (corr. decomp.); 7-chloro-2-methylxanthone, m.p. 169° (corr.); 7-phenoxy-2-methyl-xanthone 8-carboxylic acid, m.p. 270°-280 (corr.); 2-methyl-dixanthone, m.p. 249°-252° (decomp.); 7-anilino-2-methyl-xanthone, m.p. 255°-259° (corr.); 7-chloro-N-phenyl-2-methyl-pyridazonexanthone, m.p. 264°-268° (corr.)

and the 5-chloro compound, m.p. 266°-271° (corr.) (V. dem Knesebeck and Ullmann, Ber. 1922, 55, [B] 306) have also been obtained.

A general method for the preparation of the hydroxyxanthones consists of distilling a mixture of a phenol and an o-hydroxy-carboxylic acid with acetic anhydride, and this has been employed in numerous syntheses. In this manner 1-hydroxyxanthone (Michael, Amer. Chem. Soc. 5, 91; Graebe, Annalen, 54, 590), m.p. 146°-147°, 2-hydroxyxanthone (v. Kostanecki and Rutishauer, Ber. 25, 1648), m.p. 231°, 4-hydroxyxanthone (v. Kostanecki and Rutishauer), m.p. 224°, 3-hydroxyxanthone (v. Kostanecki and Nessler, Ber. 34, 3981), m.p. 243°, 3:6-di-

hydroxyxanthone (isoeuxanthone) (v. Kostanecki, *ibid.* 18, 1986), m.p. 243°, Nishikawa and Robinson (Chem. Soc. Trans. 1922, 121, 841) gave m.p. 259°, 2:5-dihydroxyxanthone (v. Kostanecki, *ibid.* 27, 1991), m.p. 280°, and gentisin and euxanthone, the two natural representatives of this group, have been prepared.

These latter are both feeble dyestuffs, and this is explained by the fact that they do not possess two hydroxyls in the ortho position relatively to one another. Graebe and Eichen-grun (Ber. 1891, 24, 969) obtained such a compound (1), 3,4-dihydroxy-xanthone by heating 2,3,4,2'-tetrahydroxy-benzophenone (2) with water at 180°-220°—

This melts at 240°, is a strong dyestuff giving an aluminium mordant yellow, and on iron mordant greyish-black shades. The position of the ortho-hydroxyl grouping is, however, of importance in that the 2,3-dihydroxy-xanthone of Liebermann and Lindenbaum (Ber. 1904, 37, 2728)—

and which is produced by the interaction of hydroxy-quinol and salicylic anhydride in the presence of sulphuric acid, is practically devoid of dyeing property. As is well known, a similar distinction is to be observed between alizarine (1) and hystazarine (2)—

and it is of interest that similar rules (cf. Liebermann and v. Kostanecki) to those which are applicable to the hydroxy-anthraquinone dyestuffs, also hold good with the xanthone colouring matters. On the other hand, it will be observed, notably in the flavonol group of colouring matters, that ortho hydroxyls are not entirely essential for dyeing property. The statement by Tschirch and Polacco (Arch. Pharm. 1900, 238, 459) that a trihydroxy-xanthone rhamnocitrin occurs in the berries of the *Rhamnus catharticus* has been shown by Oesch and Perkin (Chem. Soc. Trans. 1914, 105, 2350) to be incorrect.

A. G. P.

XANTHORHAMNIN v. GLUCOSIDES; PERSIAN BERRIES.

XANTHORRHOEA RESINS OR BALSAMS v. BALSAM.

XANTHOSTEROL $C_{31}H_{46}O$ is obtained by extracting the bark of *Xanthoxylum Budrunga* with light petroleum. Slender white needles, m.p. 213° – 214° . For colour reactions and derivatives, see Dieterle, Arch. Pharm. 1919, 257, 260; Chem. Soc. Abstr. 1920, i. 42; cf. Dieterle, Arch. Pharm. 1922, 259, 244). According to Ultée, xanthosterol is identical with lupeol, as is also the phytosterol of Oestling from *Fagara xanthoxyloides*, Lam.

XANTHOXYLUM ESSENTIAL OILS (Simonsen and Rau, Indian Forest Rec. 1922, 9, 111) The seeds of *X. alatum*, Roxb., yield an oil containing over 85 p.c. of *l*- α -phellandrene, together with small amounts of linalool and a sesquiterpene. The oil obtained from the seeds of *X. acanthopodium*, DC., has sp.gr. 0.8837 at 30° ; $n_D^{20}=1.4746$; $[\alpha]_D^{20}=+6.54^{\circ}$; sapon. value, 60.79; sapon. value after acetylation, 242.5. The chief constituents are dipentene, methyl cinnamate, and over 50 p.c. of linalool in addition to *l*- α -phellandrene and a small quantity of an aldehyde or ketone and a mixture of fatty acids.

X. Budrunga, Wall., seeds yield an oil apparently identical with that found by Semmlé to occur in *X. alatum*. The terpene present is *l*-sabinene, in addition to small quantities (Lautermann) of terpinene (J. Soc. Chem. Ind. Jan. 12, 1923, 30 A).

XANTHYDROL $C_{13}H_{16}O$, or $O\left\langle\begin{array}{c} C_6H_4 \\ C_6H_4 \end{array}\right\rangle CH\cdot OH$.

Prepared by slowly adding zinc dust to a boiling mixture of xanthone (10 grms.), NaOH (40 grms.), and alcohol (400 c.c.). Precipitated in minute needles on adding water (R. Meyer and Saul, Ber. 1893, 26, 1276). Decomposes on melting. Reproduces xanthone on heating in the air. If a methyl-alcoholic solution of xanthydrol is mixed with an aqueous solution of urea to which a large excess of acetic acid has been added and the mixture allowed to stand for two hours dioxanthidryl-urea $O(C_6H_4)_2CH\cdot NH\cdot CO$ will be deposited. The weight of this substance, after washing with alcohol and drying, may be used for estimating the amount of urea in a solution (Fosse, Hagene and Dubois, Compt. rend. 1924, 79, 214; J. Soc. Chem. Ind. 1924, 43, B. 731). Dulcin and saccharin also form crystalline condensation products with xanthydrol (cf Vol. vi. p. 4).

XARA. Trade name for acetyl-salicylic acid.

XAXAQUIN. Trade name for quinine acetyl-salicylate.

XENON. Sym. X. At.wt. 130.2.

An inert gas, discovered along with krypton in the final residues obtained after evaporating considerable quantities of liquid air (Ramsay and Travers, Proc. Roy. Soc. 1898, 63, 405). For the separation of xenon from these residues, see KRYPTON. Xenon may also be separated by passing a current of air through a spiral tube filled with glass wool and immersed in liquid air (Dewar, *ibid.* 1901, 68, 360). Xenon occurs in the gases evolved from many thermal springs (Moureu and Lepape, Compt. rend. 1909, 149, 1171).

Xenon is the least volatile and least abundant of the inert gases which exist in the atmosphere, being present only to the extent of 1 part in 170 million parts of air by volume (Ramsay,

Proc. Roy. Soc. 1903, 71, 421; 1906, 80, A, 599). It boils at -109.1° , at which temperature its density is 3.063 and its atomic volume 42.7. The critical temperature is $+16.6^{\circ}$, the critical pressure 58.2 atmospheres, and the critical density 1.115 grms. per c.c. The 'rectilinear diameter' is given by the equation

$$D_r = 1.205 - 0.003055t$$

where D_r = mean density of liquid and saturated vapour at $t^{\circ}C$. (Patterson, Cripps and Whytlaw-Gray, Proc. Roy. Soc. 1912, A, 579). At the temperature of liquid air xenon readily solidifies (Ramsay and Travers, Proc. Roy. Soc. 1901, 67, 329).

At N.T.P. 1 litre of xenon weighs 5.851 grms.; its density is therefore 65.35 ($\rho=16$) (Moore, Chem. Soc. Trans. 1908, 93, 2181; Watson, *ibid.* 1910, 97, 833). The refractive index at N.T.P. for the green mercury line ($\lambda=5461$) is 1.0007055 (Cuthbertson and Cuthbertson, Proc. Roy. Soc. 1908, 81, A, 440; 1910, 84, A, 13). At 20° the absorption coefficient is 0.1109 (Antropoff, *ibid.* 1910, 83, A, 474; Zeitsch. Elektrochem. 1919, 25, 269). For the spectrum of xenon v. Baly (Phil. Trans. 1903, A, 202, 183); Livinge and Dewar (Proc. Roy. Soc. 1901, 68, 389; Merrill, Bur. Standards, Bull. 1919, 15, 251; Collic, Proc. Roy. Soc. 1920, [A] 97, 349).

Xenon is monatomic since the ratio of its specific heats is 1.66 (Ramsay). Xenon would appear to be a mixture of isotopes, with definite evidence of five isotopes of masses 129, 131, 132, 134 and 136, and with distinct indications of a sixth component, 128, present in smaller quantity. It is possible also that there is a seventh isotope of mass 130 (Aston). For regularities in the xenon spectrum, see Sommer, Zeitsch. Physik. 1923, 13, 85.

XENOTIME. Yttrium orthophosphate YPO_4 crystallised in the tetragonal system. The crystals resemble in habit and also closely in interfacial angles those of cassiterite, rutile, zircon, thorite, tapiolite, &c. Crystals of xenotime and zircon intergrown in parallel position have been observed. There is a good cleavage parallel to the faces of the square prism. Sp.gr. 4.4–4.6; H. 4–5; colour usually brownish with resinous lustre; insoluble in acids. The yttrium earths are rich in erbia, xenotime being one of the principal sources of this rare-earth. Cerium earths are also present in small amount, but only occasionally thorina (cf. MONAZITE). Curiously, however, a supposed new earth (afterwards proved to be basic yttrium phosphate) in xenotime was called thorina by Berzelius in 1815—a name later transferred to the earth that he discovered in 1829 in thorite. Sulphuric anhydride in small amount is sometimes present in xenotime. The mineral occurs as single crystals scattered in pegmatite and granitic rocks, and is of wide distribution, though less common than monazite. It is found in sands derived from these rocks, including monazite sands. Rough opaque crystals with the form of low tetragonal bipyramids, up to an inch across, are found in the felspar quarries at several places in the south of Norway. Small transparent crystals of prismatic habit are met with in the diamondiferous sands of Minas Geraes and Bahia in Brazil. L. J. S.

XYLAN $C_8H_8O_4$, a substance contained in wheat straw and corn cobs. To obtain it, air dried wheat straw is treated in the cold with a dilute solution of ammonia for 24 hours, and the ammoniacal solution removed by decantation. The residue, after washing with water, is immersed in a 7 p.c. solution of sodium hydroxide for 48 hours, and the extract filtered through a silk cloth. To the clear brown-coloured solution an equal volume of 98 p.c. alcohol is added with constant stirring, when the xylan is precipitated, collected and washed with dilute alcohol, again dissolved in 7 p.c. sodium hydroxide solution and reprecipitated with alcohol. The separated xylan is treated with dilute hydrochloric acid, washed with dilute alcohol, and subsequently with ether and dried over sulphuric acid *in vacuo*. The yield is about 16-17 p.c. (Allen and Tollens, Ann. 1890, 260, 290; Komatsu and Kashima, Mem. Coll. of Science, Kyoto Imp. Univ. 1922, 5, [5] 307; Heuser and Braden, J. pr. Chem. 1922, [ii.] 104, 250).

Xylan is a light yellow amorphous substance, easily soluble in alkaline solutions with a specific rotation $[\alpha]_D^{25} = -78^\circ$ in 2.5 p.c. sodium hydroxide solution. Insoluble in water and alcohol. Readily hydrolysed to *lævo*-xylose when heated with 1.5 p.c. hydrochloric acid (cf. Heuser and Brunner, J. pr. Chem. 1922, [ii.] 104, 264). Gives a monoacetyl ($C_8H_7O_4(CH_3CO)$) and diacetyl derivative ($C_8H_6O_4(CH_3CO)_2$) when treated with acetyl chloride, or with glacial acetic acid, and acetic anhydride in presence of a catalyst. They are light yellow amorphous powders, soluble in chloroform but insoluble in alcohol or ether. Soluble in sodium hydroxide solution (Komatsu and Kashima, *l.c.*; Böeseken, van der Berg, and Kerstjens, Rec. trav. chim. 1916, 35, 320; Bader, J. Chem. Soc. 1896, 70, 1335).

For methyl ethers of xylan, *see* Heuser and Ruppel, Ber. 1922, 55, 2084; acetyl derivatives, Heuser and Schlosser, Ber. 1923, 56, [B] 392.

For the constitution of xylan, *see* S. Komatsu, T. Inoue and R. Nakai, The Memoirs of the College of Science, Kyoto Imperial University, Series A. vol. vii. No. 1923.

For the products of its dry distillation, *see* Heuser and Scherer, Brennstoff Chem. 1923, 4, 97; J. Soc. Chem. Ind. May 11, 1923, 393 A.

For the hydrolysis of xylan by means of dilute nitric acid, *see* E. Heuser and G. Jayme, J. prakt. Chem. 1923, [ii.] 105, 232-242, 283-287.

XYLENES, Dimethylbenzenes,

A hydrocarbon C_8H_{10} , in reality a mixture, was isolated by various investigators from the fraction of coal tar, or wood tar, boiling between 137.5° and 142° (Cahours, Compt. rend. 1850, 30, 319; Voelckel, Ann. 1853, 86, 331; Reissig, Zeitsch. für anal. Chem. 1864, 3, 9; Ritthausen, J. pr. Chem. 1854, 61, 74; Church, Phil. Mag. (4), 9, 453; Warren and Storer, J. pr. Chem. 1867, 102, 436; Fittig, Koelbrich and Jilke, Ann. 1868, 145, 129; Bull. Soc. chim. 1869, 11, 78; de la Rue and Müller, J. pr. Chem. 1857, 70, 300; Bussenius and Eisenstuck, Ann. 1860, 113, 151; Müller, Zeitsch. f. Chem. 1864, 151).

Fittig (Ann. 1870, 153, 265; Bull. Soc. chim. 1869, 12, 306) showed that the crude xylene from coal tar contained two isomeric hydrocarbons: *m*-xylene, which he had previously obtained by distilling mesitylenic acid with lime, and *p*-xylene, which he had prepared by the action of sodium on a mixture of crude bromotoluene and methyl iodide. Later, Jacobsen (Ber. 1877, 10, 1010) isolated the third isomeride from coal tar, viz. *o*-xylene, which had previously been prepared by Fittig and Bieber (Ann. 1870, 156, 239), by distilling *p*-xylic acid with lime.

Of the xylenes found in coal tar and wood tar, the *m*-isomeride exists in the greatest quantity, although the relative proportions of the three isomerides varies both with the material distilled and the temperature at which the distillation is conducted.

o-Xylene with about 5 p.c. of *p*-xylene is formed when methyl chloride is passed into warm toluene in presence of aluminium chloride. Xylenes are formed also, together with other hydrocarbons, when the vapour of turpentine oil is passed through a red-hot tube or when cymene vapour is passed through a red-hot tube, a large quantity of naphthalene, benzene and other hydrocarbons being formed at the same time (Berthelot, Bull. Soc. chim. 1867, 7, 229). Toluene and xylene have been isolated from petroleum fractions by means of liquid sulphur dioxide (Taus and Stuber, Zeitsch. angew. Chem. 1919, 32, 175).

When cracked at 760° , 100 galls. of oil derived from Pennsylvania crude petroleum yielded 3.3 galls. of benzene, 3.2 galls. of toluene, and 2.5 galls. of xylene, the maximum amount of xylene in the recovered oil being 6.8 p.c. at 815° (Egloff and Twomey, Met. & Chem. Eng. 1916, 15, 15; J. Phys. Chem. 1916, 20, 121). For the formation of the xylenes in pyrogenic acetylene condensations, *see* Meyer and Fricke, Ber. 1914, 47, 2765; Meyer and Meyer, Ber. 1918, 51, 1571).

In order to separate the isomerides, a commercial xylene, boiling at about 140° , and freed from phenols and bases by treatment with alkali and acid, is used. If only the *m*-isomeride, which is of chief technical importance, is required, the mixture is boiled with dilute nitric acid (1 part of commercial acid, D 1.4, and 2 parts of water); the *o*- and *p*-xylenes are converted into acids, whilst the *m*-isomeride is scarcely attacked (Fittig and Velguth, Ann. 1868, 148, 10). The product is distilled with steam, the distillate shaken with alkali to remove acids and nitro-xylenes, then dried and distilled. *o*-Xylene is slowly attacked in open vessels by nitric acid (D 1.075), but more readily by nitric acid (D 1.1).

Under the same conditions *p*-xylene is attacked more readily, and *m*-xylene with greater difficulty. This behaviour leads to a modification of Fittig and Velguth's method for purifying *m*-xylene, which is best carried out by boiling and constantly stirring the crude xylene with nitric acid (D 1.075), the concentration being kept constant by addition of acid. The nitro groups are eliminated subsequently by treating the product with aqueous potassium hydroxide (Konowaloff, J. Russ. Phys. Chem. Soc. 1903, 37, 530, 537). Jacobsen (Ber. 1877, 10, 1000;

1876, 11, 17) has described a method by which the three isomerides may be isolated from coal-tar xylene. The crude xylene is shaken in the cold with concentrated sulphuric acid, when *p*-xylene is scarcely attacked, whilst the *o*- and *m*-isomerides are converted into their sulphonic acids and dissolve in the acid.

In order to obtain the *o*- and *m*-xylenes, the acid solution is treated with calcium carbonate, filtered from calcium sulphate, the filtrate, containing the calcium sulphonates, is precipitated with sodium carbonate, and the sodium sulphonates allowed to crystallise. Sodium *o*-xylene sulphonate separates first, whilst the sodium salts of the two isomeric *m*-xylene sulphonic acids remain in solution.

In order to purify the *p*-xylene, it is warmed gently with fuming sulphuric acid, in which it dissolves, leaving behind a paraffin and other impurities. The three xylenes are then regenerated from their sulphonic acids by hydrolysis with concentrated hydrochloric acid at 195° (cf. Armstrong and Miller, Chem. Soc. Trans. 1884, 45, 151).

Wroblewsky (Ber. 1879, 12, 1226; Ann. 1881, 207, 91) separated *o*-xylene from its *m*-isomeride by converting the mixture into the corresponding xylidines, followed by acetylation with glacial acetic acid for 3 days. The fraction, b.p. above 320°, consists of aceto-*m*-xylidide, and the fraction, distilling up to 310°, consists of water, acetic acid, and unchanged *o*-xylidene. This method of separation is stated to yield better results than that of Jacobsen.

Nölting and Palmer (Ber. 1891, 24, 1955) have shown that commercial xylene contains ethylbenzene, and that in Jacobsen's method of separation the *p*-xylene obtained is mixed with this hydrocarbon (see also Moore and Roaf, Proc. Roy. Soc. 1908, B, 77, 80; Ward, Proc. Cambridge Phil. Soc. 1905, 13, 81; Stohmann, J. pr. Chem. 1887, (2) 35, 41). Moreover, Crafts (Compt. rend. 1892, 114, 1110) and Clarke and Taylor (J. Amer. Chem. Soc. 1923, 45, 830) have found that *p*-xylene is sulphonated readily, even in the cold, by 95 p.c. sulphuric acid.

Levinstein (J. Soc. Chem. Ind. 1884, 3, 77, 354; Ber. 1884, 17, 444) has estimated *m*-xylene in crude xylene by heating 100 c.c. of the crude material at 100° with dilute nitric acid (40 c.c. acid 80°Tw., and 60 c.c. of water) for 1-1½ hours, or until red fumes are no longer evolved. The hydrocarbons are separated from the acid, treated with an excess of sodium hydroxide and steam distilled, or thoroughly washed with sodium hydroxide to remove the toluic acid or nitro-toluic acids formed. The *m*-xylene and paraffins contained in the distillate are separated from the aqueous layer, treated with 1½ times the volume of concentrated sulphuric acid, when the *m*-xylene is dissolved. In order to estimate *p*-xylene, 100 c.c. of the crude xylene are shaken with 120 c.c. of concentrated sulphuric acid to dissolve the *o*- and *m*-isomerides. The volume of the residual *p*-xylene and other hydrocarbons having been noted, the liquid is then treated with an equal bulk of fuming sulphuric acid (20 p.c. SO₃) to dissolve the *p*-xylene. The *p*-xylene may also be separated from the paraffins without converting the former into its sulphonic acid.

This is effected by steam distillation and fractionation, the fraction boiling below 138° on keeping in a freezing mixture deposits pure *p*-xylene. This method does not give good results with a very impure product, as toluene, cymene, &c., are all attacked by nitric acid and sulphuric acid; and in such cases it is better to convert the *o*- and *m*-xylene sulphonic acids into their sodium salts, which can be separated by recrystallisation.

The accuracy of the above methods has been questioned by Reuter (Ber. 1884, 17, 2028), for it has been shown by Brückner (Ber. 1876, 9, 406), Wroblewsky (Ber. 1879, 12, 1226), Ador and Rilliet (Ber. 1879, 12, 2300), that pure *m*-xylene cannot be obtained by treating a mixture of xylenes with dilute nitric acid, whilst stronger acid, as recommended by Levinstein, attacks *m*-xylene, although more slowly than the isomerides. A full account of Reuter's method (Chem. Zeit. 1889, 13, 830, 850) for separating *o*-, *m*-, and *p*-xylene is given in J. Soc. Chem. Ind. 1889, 8, 874. The method employed by Friedel and Crafts (Compt. rend. 1885, 101, 1218; 1891, 114, 1110; see also Eng. Pat. 8665 of 1898) for separating ethylbenzene and the three xylenes depends upon the fact that dry bromine containing 1 p.c. of iodine converts all the xylenes completely into tetrabromoderivatives, and ethylbenzene into a dibromoderivative, and the same authors give a method of separating the xylene by means of sulphuric acid, for the details of which the original communications should be consulted.

It is thus seen that the above methods for the separation of the xylenes are both contradictory and unsatisfactory. A more recent method of separation has been worked out by Clarke and Taylor (J. Amer. Chem. Soc. 1923, 45, 830), and consists of four series of operations: (1) fractional distillation; (2) selective sulphonation; (3) fractional crystallisation of sulphonic acids or their salts; (4) selective hydrolysis of the sulphonic acids at different temperatures. *m*-Xylene, which forms by far the largest proportion of coal-tar xylene, can be obtained in a high state of purity by distillation alone. The isomeric *o*- and *p*-xylenes may be removed by boiling the mixture with dilute nitric acid. The product is then washed with water and alkali, distilled first in a current of steam, and finally under atmospheric pressure with the use of a fractionating column. The hydrocarbon is then sulphonated by stirring at 95° with half its volume of concentrated sulphuric acid, the resulting acid solution separated from unsulphonated material, diluted with an equal volume of concentrated sulphuric acid and twice its volume of water, and distilled in a current of steam with the aid of heat to increase the concentration and raise the temperature. The first runnings consist of water and suspended unsulphonated hydrocarbons, the fraction distilling between 110°-120° is pure *m*-xylene, b.p. 138°-139°. Pure *o*-xylene may be obtained from commercial *o*-xylene (95 p.c. of which distils at 143°-144°) by treating 5 litres (4400 grs.) of the latter with 2½ litres of concentrated sulphuric acid at 95° for four hours with stirring. After cooling, the layer of unsulphonated material is removed, and the sulphonic acid layer is diluted with

3 litres of water and neutralised with 40 p.c. sodium hydroxide solution. The solution of the sodium salt is centrifuged, and the solid recrystallised three times from water, when the pure sodium salt, long flat needles, is obtained. To obtain the hydrocarbon, sodium *o*-xylene sulphonate is dissolved in the minimum amount of cold water to which an equal volume of concentrated sulphuric acid is added subsequently. The mixture is heated to 110° and steam distilled with external heating until the temperature rises to about 130°. Practically the whole of the *o*-xylene distils between 110° and 120°. The hydrocarbon is separated from the distillate and distilled, when a 45 p.c. yield (1980 grs.) of pure *o*-xylene, b.p. 144°–145°, is obtained. To prepare pure *p*-xylene, 10 kg. of commercial *p*-xylene (91 p.c. of which distils between 136° and 137°) are treated with an equal volume of concentrated sulphuric acid at a temperature of 15°–20° with stirring for 5–6 hours, the undissolved hydrocarbons (5–6 litres) being treated again in a similar manner. The portion which remains undissolved after this treatment is mixed with an equal volume of concentrated sulphuric acid and stirred for 5 hours at 95°. After cooling, the lower acid layer is separated and mixed cautiously with an equal volume of concentrated hydrochloric acid. Heat is evolved, and as the solution cools the *p*-xylene sulphonic acid crystallises in fine plates, which are recrystallised from a quarter of their weight of hot distilled water. The mother liquors contain *p*- and *m*-xylene sulphonic acids. The recrystallised *p*-acid, which still contains a little *m*-xylene sulphonic acid, is dissolved in the minimum amount of water and mixed with an equal weight of concentrated sulphuric acid, heated to 120° and steam distilled, allowing the temperature to rise to 145°, when *m*-xylene distils. The temperature is then raised gradually to 170°, the greater part of the *p*-xylene distilling at 150°–155°. The oil in the distillate is separated, dried over calcium chloride, and cooled to 5°, when the greater part solidifies. The supernatant liquor is removed and the crystalline *p*-xylene, m.p. 10°–12°, distils completely at 136.5°–137°. The yield from 20 kg. of the commercial product is 2847 grms. (14.2 p.c.). No evidence of the presence of ethylbenzene was obtained. The unsulphonated material present in xylene, usually referred to as consisting of paraffins, is probably a mixture of cyclohexane derivatives, such as the hexahydroxylenes. Patterson, McMillan and Somerville (Chem. Soc. Trans. 1925, 125, 2488) separate the three xylenes as follows: Coke-oven xylene-b.p. 137°–141°, is shaken with concentrated sulphuric acid for about three-quarters of an hour. The acid liquid contains *m*-xylene 4-sulphonic acid and *o*-xylene 4-sulphonic acid. *p*-Xylene remains undissolved. Water is added slowly to the acid and the pasty crystals formed are filtered and heated in a current of steam at 150°–200° when *m*-xylene distils. The mixed *o*- and *m*-xylene 4-sulphonic acids are separated by fractional crystallisation of their calcium salts from water. The solubility of calcium *o*-xylene sulphonic acid increases, whilst that of calcium *m*-xylene sulphonic acid decreases with rise of temperature. According to P. Dekker (Chem. Weekblad, 1923, 20, 575), samples of xylene

which, after boiling for 24 hours, left on distillation 5 grms. of residue per 100 c.c. gave strong reactions for aldehydes.

The three xylenes may also be separated by freezing with liquid air and allowing the solid to melt slowly under suction (Fischer, Zeitsch. Elektrochem. 1910, 16, 161). The commercial fractional separation of benzene, toluene, and the xylenes has been studied by Butler and Popham (J. Soc. Chem. Ind. 1918, 37, 220 T), and James (*ibid.* 1916, 35, 236).

Commercial xylene should have been previously washed with sulphuric acid, and should, therefore, give only a pale-brown coloration with concentrated sulphuric acid. The boiling-point of the product should lie within a few degrees; thus not more than 10 p.c. should distil below 130°, and not more than 10 p.c. above 140.5°, the remainder passing over between these temperatures.

The xylene of commerce is a product of very variable composition. The relative proportion of the three isomerides varies in different samples, and as these three compounds have almost identical boiling-points, the boiling-point of such a mixture affords no criterion of its composition. The value of a commercial xylene depends on the quantity of *m*-xylene which it contains.

To identify *m*- and *p*-xylenes in a mixture of the three isomerides, 50 c.c. of the mixture may be heated with a mixture of chromic and sulphuric acids, whereby *o*-xylene is completely oxidised to carbon dioxide, whereas *m*-xylene yields iso-phthalic acid and *p*-xylene yields terephthalic acid (Worstell and Burwell, Amer. Chem. J. 1897, 19, 830).

Methods for the quantitative estimation of the three xylenes in the commercial product have been devised by Levinstein (*l.c.*), Friedel and Crafts (*l.c.*), Reuter (Ber. 1884, 17, 2028; J. Soc. Chem. Ind. 1884, 3, 626; 1889, 8, 874; Chem. Zeit. 1889, 13, 830); in light oils by Egloff (Met. & Chem. Eng. 1917, 16, 259); in solvent naphtha by Spielmann and Jones (J. Soc. Chem. Ind. 1917, 36, 489); in gases by Davis, Davis and MacGregor (J. Ind. Eng. Chem. 1918, 10, 712).

The use of xylene for stripping illuminating gas to remove naphthalene has been investigated by Eitner (J. für Gasbeleucht. 1899, 42, (6) 89; (9) 148; (26) 425); Breithkopf (*ibid.* 1899, 42, (40) 671); Leather (J. Gas Lighting, 1899, 73, 1734); Irwin (J. Soc. Chem. Ind. 1899, 18, 109); Young (J. Gas Lighting, 1899, 74, 755).

For the degradation of xylene into lower homologues in the presence of catalysts, &c., see Houlehan (U.S. Pats. 1334033, 1337317 of 1920), Fischer and Niggemann (Ber. 1916, 49, 1475). When xylene is submitted in the form of vapour to a temperature of 600°–850° at a pressure capable of being reduced to half an atmosphere, a yield of 30 p.c. of toluene is obtained (Synthetic Hydro-Carbon Co., Fr. Pat. 479786 of 1915; see also Eng. Pats. 9163, 13100, of 1915; Fr. Pat. 479211 of 1915).

The xylenes and similar coal-tar hydrocarbons may be rendered miscible with water without separation by heating them with a suitable soap and a minimum quantity of water. Thus when 40 kg. of oleic acid, 40 kg. of potash

lye (20°B.) and 20 kg. of *o*-xylene are heated together with agitation until homogeneous, the product forms a clear solution containing up to 10 p.c. of xylene. The products are also soluble in sea water and may be used for washing and other purposes, including the drilling, turning, or other similar working of metals (Simon and Dürkheim, Fr. Pat. 422953 of 1910; J. Soc. Chem. Ind. 1911, 30, 610).

The autoxidation of xylene, in admixture with an aromatic nitro-hydrocarbon, in the presence of sunlight has been studied by Suida (Ber. 1914, 47, 467; Monatsh. 1912, 33, 1268), and the photobromination of xylene by Swenson (Zeitsch. wiss. Photochem. 1921, 20, 206).

When the xylenes are oxidised with chromic acid in the presence of acetic acid and sulphuric acid, the corresponding tetracetate of phthalaldehyde is formed (Thiele and Winter, Ann. 1900, 311, 353). Like other homologues of benzene, xylene reacts with cellulose forming desoxyxins (Nastukoff, Zeitsch. Farb. Ind. 1907, 6, 70), and the xylenes react with 96 p.c. selenic acid to form selenonic acids (Anschütz, Kallen and Riepenkröger, Ber. 1919, 52, 1860).

Crude coal-tar xylene, containing paraffins and other hydrocarbons, was formerly used only under the name of solvent naphtha. At present purified xylene is used for the preparation of xylidine for use in the manufacture of Xylidine Scarlet and other azo-dyes.

Ring substituted chloro-xylenes can be further chlorinated in the side-chain at high temperatures (100°–130°) in the presence of light. The products may be converted by concentrated sulphuric acid into chlorinated dialdehydes or aldehyde-carboxylic acids, which, on condensation with *o*-cresotinic acid, for example, yield leuco-compounds of the triphenylmethane series. On oxidation with sodium nitrite in concentrated sulphuric acid solution dyes are obtained which dye wool from an acid bath brownish-red, converted by after-chroming into bright violet-blue, very fast to washing and milling (Schmidlin and M. Fischer, U.S. Pat. 1219166 of 1917; cf. Ransford, Eng. Pat. 114645 of 1917).

o-Xylene, from coal-tar and wood-tar; by distilling *p*-xylic acid with lime (Fittig and Bieber, Ann. 1870, 156, 231; Bull. Soc. chim. 1870, (2) 13, 268); from *o*-bromotoluene and methyl iodide in presence of sodium, followed by fractionating the product over sodium (Jannasch and Hübner, Ann. 1873, 170, 117; Bull. Soc. chim. 1872, (2) 18, 334; Reymann, *ibid.* 1876, (2) 26, 532); by heating cantharidin with excess of phosphorus pentasulphide (Piccard, Ber. 1879, 12, 580); by passing methyl iodide through a mixture of toluene and aluminium chloride at 85° (Jacobsen, Ber. 1881, 14, 2628).

Liquid, b.p. 144° (corr.), m.p. –25° (Fischer, Zeitsch. Elektrochem. 1910, 16, 161), or –28.5° (Colson, Ann. Chim. Phys. 1885, (6) 6, 128); b.p. 141.9°; D_{20}^0 0.8932 (Pinette, Anp. 1888, 243, 50; cf. Hirsch, Ann. Phys. Chem. 1899, (2) 69, 456); b.p. 141°/756.2 mm.; D_{41}^{141} 0.7559; capillarity constant at b.p. $\alpha^2=4.437$ (Schiff, Ann. 1896, 236, 36; Rob and Feustel, Ann. der Phys. 1904, (4) 16, 61; cf. Neubeck, Zeitsch.

physikal. Chem. 1887, 1, 660); D_4^0 0.8903; D_{15}^{15} 0.818. For vapour tension, see Woringer (Zeitsch. physikal. Chem. 1900, 34, 263); critical temperature, Altschul (*ibid.* 1893, 11, 950), Brown (Chem. Soc. Trans. 1906, 89, 311); latent heat of vaporisation, Brown (*ibid.* 1906, 87, 2657); dielectric constant and refractive index, Landolt and Jahn (Zeitsch. physikal. Chem. 1892, 10, 300), Drude (*ibid.* 1897, 23, 309), Brühl (J. pr. Chem. 1894, (2) 50, 140); magnetic properties, Schönrock (Zeitsch. physikal. Chem. 1893, 11, 785), Perkin (Chem. Soc. Trans. 1896, 69, 1241; 1900, 77, 267); absorption spectrum, Groebe (Zeitsch. wiss. Photochem. 1905, 3, 376), Mies (*ibid.* 1910, 8, 287), Hartley (Chem. Soc. Trans. 1885, 47, 685), Baly and Ewbank (*ibid.* 1905, 87, 1347); molecular refraction and dispersion, Gladstone (Chem. Soc. Trans. 1891, 59, 290). *o*-Xylene when oxidised with dilute nitric acid yields *o*-toluic acid, and on treatment with a hot solution of potassium permanganate, phthalic acid is formed (Claus and Preszcek, Ber. 1886, 19, 3083), whilst chromic acid completely destroys it. For the oxidation of *o*-xylene, see also Thiele (Ann. 1900, 311, 358), Clausner (Ber. 1905, 38, 2860), Law and F. M. Perkin (Chem. Soc. Trans. 1907, 91, 258). When heated with hydrogen iodide at 250°–280°, *o*-xylene yields toluene, methyl- and dimethylcyclohexane and methylated pentamethylene (Markownikow, Ber. 1897, 30, 1218). *o*-Xylene, when treated with aluminium chloride at 100° in the presence of hydrogen chloride, yields principally *m*-xylene, together with smaller quantities of benzene, toluene, *p*-xylene, pseudocumene and mesitylene (Heise and Tohl, Ann. 1892, 270, 155; Friedel and Crafts, Compt. rend. 1885, 100, 100, 692; Jacobsen, Ber. 1881, 14, 2626; 1885, 18, 338; Anschütz and Immendorff, *ibid.* 1884, 17, 2816; 1885, 18, 657). Nitrogen peroxide reacts with *o*-xylene to yield nitro-*o*-xylene, *p*-toluic acid, phthalic acid, and oxalic acid (Leeds, Ber. 1881, 14, 482). On methylation, *o*-xylene yields exclusively pseudocumene (Jacobsen). Hot dilute nitric acid yields nitro-derivatives, substituted in the side-chain. When oxidised electrolytically in presence of acetone, *o*-xylene yields *o*-toluic aldehyde (Law and F. M. Perkin, Trans. Faraday Soc. 1904, 1), and when heated for several hours with hydroxylamine in the presence of aluminium chloride or ferric chloride, it yields *o*-4-xylidine (Graebe, Ber. 1901, 34, 1778). It also condenses with triphenylmethyl yielding a complex $[(C_6H_5)_3C]_2 + C_8H_9(CH_3)_2$ (Gomberg and Conc, Ber. 1905, 38, 1333).

Phosphorus pentachloride at 200° reacts with *o*-xylene forming $C_8H_4(CCl_2)_2CHCl_2$ (Colson and Gautier, Bull. Soc. chim. 1886, (2) 45, 507). Bromine in the dark forms 4-bromo-*o*-xylene, whilst in direct sunlight the products are xylid bromide and xylidene bromide (Schramm, Ber. 1885, 18, 1278).

o-Xylene when monobrominated at 130° yields chiefly monobromo-derivatives, together with a small quantity of unchanged material and *o*-dibromo-derivatives, whilst, on dibromination at 130°, the product consists chiefly of dibromo-, together with mono- and tribromo-derivatives. The method employed by Radziszewski and Wispek (Ber. 1882, 15, 1743), Löw (Ann. 1885,

231, 363), and Pellagrin (Rec. trav. chim. 1899, 18, 458), in which the vapour of the halogen was allowed to react with the boiling hydrocarbon, is not satisfactory, owing to the difficulty of preventing the hydrogen bromide evolved from carrying some of the bromine vapour away with it. The method adopted by Atkinson and Thorpe (Chem. Soc. Trans. 1907, 91, 1687) yields more satisfactory results. A litre Geissler flask with a ground-in air condenser is fitted with a dropping funnel fused into the neck of the flask and reaching below the level of the hydrocarbon to be brominated. *o*-Xylene when brominated with a mixture of nitric and hydrobromic acids, or preferably with a mixture of bromine and nitric acid, yields bromo-*o*-xylene and tetrabromo-*o*-xylene, together with *o*- and *p*-toluic acids (Datta and Chatterjee, J. Amer. Chem. Soc. 1916, 38, 2545). *o*-Xylene when treated with aqua regia yields a monochloro-, 4:5-dichloro-, and the tetrachloro-derivative (Datta and Fernandes, *ibid.* 1916, 38, 1809).

When *o*-xylene bromoacetyl bromide is treated with aluminium chloride in carbon disulphide solution, 4-*o*-xylyl bromomethyl ketone is obtained, which is probably identical with the substance prepared by Armstrong and Kipping (Chem. Soc. Trans. 1893, 63, 86) by brominating *o*-xylyl methyl ketone (Jacobs and Heideberger, J. Biol. Chem. 1915, 21, 819).

Well-cooled *o*-xylene, when treated with the vapours of sulphuric anhydride at a temperature below 30°, yields di-*o*-xylyl-*m*-(?)-sulphone, brilliant plates, m.p. 158°–159° (Zorn and Brunel, Compt. rend. 1894, 119, 1224).

4-Cyan-*o*-xylin $[C_6H_4(CH_3)_2CN]_2$ is formed from *o*-xylene by the action of cyanogen bromide in presence of aluminium chloride. It sinters at 204°, melts at 210° (decomp.), and on treatment with hydrochloric acid at 220° yields *p*-xylic acid (Scholl and Nörr, Ber. 1900, 33, 1052).

o-Xylyl boro-chloride melts at 0° and boils at 212°, and the corresponding acid forms colourless needles, m.p. 190°5', and the oxide melts at 226° (Michaelis and Thévenot, Ann. 1901, 315, 19).

o-Xylylene hydrazine $C_6H_4 \begin{smallmatrix} CH_2 \\ | \\ CH_2 \end{smallmatrix} N \cdot NH_2$ is prepared by reducing nitroso-dihydro-isindole with zinc dust in dilute acetic acid solution (Fränkel, Ber. 1900, 33, 2808).

o-Chloro-*o*-xylene, *o*-xylyl chloride; by chlorinating boiling *o*-xylene (Reynian, Bull. Soc. chim. 1876, (2) 26, 534); in an impure condition by heating *o*-xylyl alcohol with concentrated hydrochloric acid (Colson, Ann. Chim. Phys. 1885, (6) 6, 117; Compt. rend. 1884, 98, 1543; 1884, 99, 40); by the action of chlorine on *o*-xylene in sunlight (Radziewanowski and Schramm, Akad. Wiss. Krakau, 1898, 61). Oil, b.p. 197°–199° (R.), or 195°–203° (R. and S.). When treated with aqueous lead nitrate it yields *o*-tolualdehyde.

o-o-Dichloro-*o*-xylene, *o*-xylylene chloride; from phthalyl alcohol and concentrated hydrochloric acid (Hessert, Ber. 1879, 12, 648; Colson, Bull. Soc. chim. 1885, (2) 43, 7; Ann. Chim. Phys. 1887, (6) 11, 25); in small yield by chlorinating 1 mol. of *o*-xylene with 1 mol. of chlorine in sunlight, or as chief product when 2 mols. of chlorine are used (R. and S.); by heating *o*-xylene with phosphorus pentachloride

at 180°–200° (Colson and Gautier, Bull. Soc. chim. 1886, (2) 45, 6; Compt. rend. 1885, 101, 1064; 1887, 104, 428; Strassmann, Ber. 1888, 21, 578).

Triclinic crystals (Wilk, Ber. 1885, 18, 2879), or long prisms, m.p. 55°, b.p. 240°–260° (R. and S.), or m.p. 54°6'–54°8', b.p. 239°–241°, D_0^{20} 1.393.

Tolyldene chloride $CH_3 \cdot C_6H_4 \cdot CHCl_2$ (?); by chlorinating heated *o*-xylene (Rayman). Tables, m.p. 103°; b.p. 225°, converted into phthalaldehyde (?) by boiling with lead nitrate solution. This compound, however, is stated by Colson (Compt. rend. 1884, 98, 1543) to be more probably 1:4-dichloro-xylene.

Symm.-o-tetrachloro-o-xylene $C_6H_4(CHCl_2)_2$; by the action of chlorine on *o*-xylene, initially at 140° and finally at 160°–170° (Hjelt, Ber. 1885, 18, 2879); from *o*-xylene and 4 mols. of phosphorus pentachloride at 150° (Colson and Gautier, Ann. Chim. Phys. 1887, (6) 11, 25). Triclinic crystals (Wilk), m.p. 89°, b.p. 273°–274° (H.); m.p. 86° (C. and G.); D_0^{20} 1.601 (Colson, Bull. Soc. chim. 1886, 46, 2). When heated with water at 200°–210° it yields phthalaldehyde.

Penta-o-chloro-o-xylene, $C_6H_4(CCl_2)(CHCl_2)$; as the chief product when *o*-xylene is heated in a sealed tube at 100° with a large excess of phosphorus pentachloride (Colson and Gautier, *l.c.*; Compt. rend. 1886, 102, 689). Monoclinic crystals, m.p. 53°6'. When left in contact with dilute aqueous potassium hydroxide it loses the whole of its chlorine and is converted into phthalaldehydic acid.

o-Xylene hexachloride $C_6H_4(CH_2)_2Cl_6$; by chlorinating *o*-xylene in sunlight (R. and S.). Rhombic crystals, m.p. 194°5', b.p. 260°–266°.

3-Chloro-*o*-xylene; together with the 4-chloro-isomeride by chlorinating ice-cold *o*-xylene in presence of 5 p.c. of iodine (Krüger, Ber. 1885, 18, 1755), or iron (Claus and Bayer, Ann. 1893, 274, 304). The isomerides may be separated by means of their barium sulphonates (K.). Colourless refractive oil, b.p. 189°5'.

4-Chloro-*o*-xylene; *see* above. Oil, b.p. 191°5'; D_{15}^{15} 1.0692 (K.); or b.p. 195° (Claus and Gronweg, J. pr. Chem. 1891, (2) 43, 252; *cf.* Claus and Kautz, Ber. 1885, 18, 1367). Its barium sulphonate is more soluble than that of 3-chloro-*o*-xylene (K.).

3:5-Dichloro-*o*-xylene; together with 3:5:6-trichloro-*o*-xylene when 3:5-dichloro-1:1-dimethyl- Δ^2 :4-cyclohexadiene is treated in cold chloroform solution with chlorine, followed by heating the product to 150°–180° for 1 hour (Hinkel, Chem. Soc. Trans. 1920, 117, 1296); by the action of excess of phosphorus pentachloride on 3:5-dichloro-1:1-dimethyl- Δ^2 :4-dihydrobenzene in chloroform solution (Crossley and Le Sueur, Chem. Soc. Trans. 1902, 81, 1533); in small quantities together with the above dichlorodimethyldihydrobenzene by the action of phosphorus pentachloride on dimethyldihydroresorcinol (Crossley and Le Sueur, Chem. Soc. Trans. 1903, 83, 110); together with 3:5-dichloro-6-bromo-*o*-xylene by treating 3:5-dichloro-1:1-dimethyl- Δ^2 :4-dihydrobenzene with 1 mol. of bromine in chloroform solution (Crossley, *ibid.* 1904, 85, 264); together with dimethylmalonic

acid, isobutyric acid, 3:5-dichlorophthalic acid, dichlorotribromo - dimethyltetrahydrobenzene and 3:5-dichloro-6-bromo-*o*-xylene by oxidising dichlorodibromo - dimethyltetrahydrobenzene with potassium permanganate (C.).

Faintly yellow, highly refractive liquid, b.p. 129°/23 mm. or 226°/atm., which on cooling solidifies to flaky needles, m.p. 3°-4°. On oxidation with dilute nitric acid under pressure it yields a dichlorotoluic acid, long glistening needles, m.p. 184°-185°, and 3:5-dichlorophthalic acid (C.; C. and S.).

4:5-Dichloro-*o*-xylene; together with higher chlorinated homologues by passing dry chlorine through well-cooled *o*-xylene containing 10 p.c. of iodine (Claus and Kautz; Claus and Gronweg). Oil, b.p. 227°, solidifying on cooling to crystals, m.p. 3°. When heated at 200° with nitric acid (D 1.15) in a sealed tube it yields 4:5-dichlorophthalic acid. Koch (Ber. 1890, 23, 2318) states that a solid dichloro-*o*-xylene, long hard needles, m.p. 73°, is obtained together with the liquid isomeride when *o*-xylene is chlorinated.

Trichloro-*o*-xylene (Claus and Kautz), long colourless needles which sublime, m.p. 93°, b.p. 265° (decomp.). When oxidised with nitric acid (D 1.15) at 200° in a sealed tube it yields trichlorophthalic acid.

3:4:5-Trichloro-*o*-xylene; by heating pentachlorodimethylcyclohexene; together with other substances when 3:5-dichloro-1:1-dimethyl-Δ²:4-cyclohexadiene is treated in chloroform solution with excess of chlorine at low temperatures. Felt-like needles, m.p. 96° (Hinkel, Chem. Soc. Trans. 1920, 117, 1296).

3:5:6-Trichloro-*o*-xylene; see 3:5-dichloro-*o*-xylene; together with the 3:4:5-trichloroisomeride, 3:4:5:6-tetrachloro-*o*-xylene and 2:3:3:4:5-pentachloro-1:1-dimethyl-Δ⁵-cyclohexene, by chlorinating 3:5-dichloro-1:1-dimethyl-Δ²:4-cyclohexadiene in chloroform solution at low temperatures (Hinkel). Short colourless crystals, m.p. 47.5°.

3:4:5:6-Tetrachloro-*o*-xylene; see above; by chlorinating well-cooled *o*-xylene containing 10 p.c. of iodine (C. and K.); by chlorinating 3:4:5- or 3:5:6-trichloro-*o*-xylene in chloroform solution in presence of iron (H.); by heating pentachlorodimethylcyclohexene on the water-bath with fuming nitric acid (H.). Long slender glistening needles, m.p. 223°-224° (H.), or 215° (C. and K.). It is not oxidised when heated at 200° with nitric acid in a sealed tube; chromic acid mixture completely destroys it. It sublimes, and is non-volatile with steam (C. and K.).

Tetrachloroxylylene oxide; by reducing tetrachlorophthalic acid with hydriodic acid and red phosphorus (Graebe, Ann. 1887, 238, 318). Long needles, m.p. 218°.

ω-Bromo-*o*-xylene, *o*-xylyl bromide; by brominating boiling *o*-xylene (Radziszewski and Wispek, Ber. 1882, 15, 1747; 1885, 18, 1281; Atkinson and Thorpe, Chem. Soc. Trans. 1907, 91, 1687); or by brominating cold *o*-xylene exposed to direct sunlight (Schramm, Ber. 1885, 18, 1278; Colson, Ann. Chim. Phys. 1885, (6) 6, 115; Bull. Soc. chim. 1885, (2) 43, 6). Prisms or quadratic plates m.p. 21°, b.p. 216°-217°/742 mm.; D₂₅ 1.3811. With potassium thiocyanate it yields *o*-xylyl thiocyanate (Strzelecka, Bull. Acad. Sci. Cracow, 1909, 731). With

methylaniline it yields *o*-xylylmethylaniline, m.p. 34°, b.p. 200°/35 mm. (von Braun, Ber. 1910, 43, 1353), and with potassium phthalimide it yields *o*-xylyl-phthalimide, m.p. 148°-149° (Strassmann, Ber. 1888, 21, 576). The chief product obtained when magnesium acts on an ethereal solution of a xylyl bromide is the corresponding dimethyldibenzyl, and only a small amount of organo-magnesium compound is formed (Carré, Compt. rend. 1909, 148, 1108; Bull. Soc. chim. 1909, (4) 5, 486).

ω-Dibromo-*o*-xylene, *o*-xylylene bromide; by heating *o*-xylene with 2 mols. of bromine at 150°-155°, or better at 125°-130° (Bacayer and Perkin, Ber. 1884, 17, 123; Perkin, Chem. Soc. Trans. 1888, 53, 5; cf. Atkinson and Thorpe, *ibid.* 1907, 91, 1687; Radziszewski and Wispek, Ber. 1882, 15, 1743; 1885, 18, 1278 by the action of 2 mols. of bromine on cold *o*-xylene in presence of direct sunlight (Schramm, Ber. 1885, 18, 1278; Colson, Ann. Chim. Phys. 1885, (6) 6, 105; Compt. rend. 1887, 104, 428; 1884, 98, 1543).

It melts at 94.5°-94.0°, or 93° (B.), and forms large glistening rhombic crystals, *a*:*b*:*c* = 0.8581:1:0.5014. It reacts with triethylphosphine forming *o*-xylylenetriethylphosphonium bromide, colourless crystals, m.p. 250°-250.5° (Partheil and Gronover, Ber. 1900, 33, 606); with alcoholic potassium hydrosulphide to yield *o*-xylylene hydrosulphide, m.p. 45°-46°, b.p. 160°/20 mm., which is converted by methylene iodide and sodium ethoxide into *o*-xylylene-methylene mercaptal, m.p. 152°-153° (Kötz and Sevin, Ber. 1900, 33, 729); with aniline in chloroform solution to yield 2'-phenyldihydroisindole C₈H₄:(CH₂)₂:NC₆H₅, m.p. 165°; with secondary amines NHR₂' or NH-R'' it forms substituted ammonium bromides of the type C₈H₄:(CH₂)₂:NR', Br or C₈H₄:(CH₂)₂:NBr·R'', and these react with a molecule of the same or another amine at 200° yielding diacid bases of the type NR'₂·CH₂·C₈H₄·CH₂·N·R''; with tertiary amines, it forms substituted diammonium bromides of the type C₈H₄(CH₂)₂·NR'''·Br₂ (Leser, Ber. 1884, 17, 1824; Scholtz, Ber. 1898, 31, 414, 627, 1154, 1700, 1707; Partheil and Schumacher, *ibid.* 591). When treated with potassium hydroxide, *o*-xylylene bromide yields *o*-xylylene oxide C₈H₄<CH₂>O, b.p. 192° (Willstätter and Veraguth, Ber. 1907, 40, 957), and when heated at 120° with ten times its weight of concentrated ammonia for 6 hours it yields di-xylyleneammonium bromide

whilst at temperatures above 120°, preferably at 170° for 8 hours in a sealed tube, a secondary base, apparently of the composition

m.p. 79°-80°, b.p. 130°-135°/12 mm., is formed (Scholtz, Ber. 1891, 24, 2402). An alcoholic solution of *ω*-dibromo-*o*-xylene on treatment with an aqueous solution of potassium sulphide yields *o*-xylylene sulphide C₈H₄<CH₂>S, and on boiling with a large excess of alcoholic potassium hydroxide for 1½ hours it yields *o*-xylylene diethyl-ether C₈H₄(CH₂OC₂H₅)₂ (Leser, Ber. 1884, 17, 1824). When boiled for a

long time with excess of potassium iodide, it is *o*-xylene di-iodide (Leser).

When *o*-xylene bromide and *o*-xylene mercaptan are boiled with alcoholic sodium ethoxide cyclo-diithiodi-*o*-xylene, colourless slender needles, m.p. 234°–236°, is formed (Autenrieth and Brüning, Ber. 1903, 36, 183). For further condensations of *o*-xylene bromide, see Scholtz (Ber. 1910, 43, 2304; 1914, 47, 2162). With potassium thiocyanate it yields *o*-xylene thiocyanate (Strzelecka, Bull. Acad. Sci., Cracow, 1909, 731); with allylamine it yields allyl-dihydroisindole (von Braun, Ber. 1910, 43, 1353); with sodium iodide in acetone solution it yields *o*-xylylenedi-iodide, m.p. 109° (Finkelstein, Ber. 1910, 43, 1528).

ω-ω'-Tribromo-o-xylene; by brominating heated *o*-xylene. Colourless glistening plates, m.p. 97° (Atkinson and Thorpe).

Symm.-ω-tetrabromo-o-xylene, $C_8H_4(Br)_4$; by the gradual addition of 4 mols. of bromine to *o*-xylene heated to 140° (Gabriel and Muller, Ber. 1895, 28, 1830). Crystals, m.p. 115°–117°, which form an addition product with methyl iodide, pointed yellow needles, m.p. 235°–240° (G. and M.). When boiled with potassium oxalate and dilute alcohol for 24 hours it forms *o*-phthalaldehyde, yellow needles, m.p. 56°–56.5° (Thiele and Gunther, Ann. 1906, 347, 106).

3-Bromo-o-xylene; by the steam distillation of a solution of barium 3- or 6-bromo-*o*-xylene 4-sulphonate in excess of sulphuric acid. The product is purified by resulphonation and regeneration from the sodium salt (Stallard, Chem. Soc. Trans. 1906, 89, 808). Colourless highly refractive liquid, b.p. 213.8°; D_{15}^{25} 1.382.

4-Bromo-o-xylene; formed by the action of bromine on cold *o*-xylene in the presence of iodine in the dark (Jacobsen, Ber. 1884, 17, 2372; Schramm, *ibid.* 1885, 18, 1278). The product is purified by conversion into the barium sulphonate. Liquid, solidifying below 0° to a brown mass, m.p. –0.2°, b.p. 214.5°/760 mm.; D_{15}^{25} 1.3693 (J.). When boiled with dilute nitric acid it yields bromo-*o*-toluic acid, and with the lead salt of thiophenol it yields *α*-phenyl-*o*-xylyl sulphide $[(CH_3)_2S=1:2:4]$. Oil, b.p. 181.5°/11 mm.; D_4^{20} 1.0962 (Bourgeois, Ber. 1895, 28, 2312).

3(?)4-Dibromo-o-xylene; together with the 4, 5-dibromo-isomeride by the action of bromine on 4-bromo-*o*-xylene in the presence of iodine (Jacobsen, Ber. 1884, 17, 2372). Oil, solidifying on cooling to a hard crystalline mass, m.p. 6.8°, b.p. 277°; D_{15}^{25} 1.7842. The isomerides may be separated by crystallisation from alcohol.

4:5-Dibromo-o-xylene; as the chief product in the above reaction (J.); together with 4-bromo-*o*-xylene and 5- or 3-bromo-*o*-xylene 4-sulphonic acid by treating an aqueous solution of *o*-xylene 4-sulphonic acid at about 40° with a solution of bromine in hydrochloric acid (Kelbe and Stein, Ber. 1886, 19, 2137). Large rhombic tables or long needles, subliming to large thin plates, m.p. 88°, b.p. 278° (cf. Crossley and Smith, Chem. Soc. Trans. 1913, 103, 989). *4:5-Dibromo-o-xylene*, when heated with concentrated sulphuric acid at 215°, yields *3:4-dibromo-o-xylene* (Koch, Ber. 1890, 23, 2318).

3:4:5-Tribromo-o-xylene; from *3:5-*

dibromo-o-4-xylylene by the Sandmeyer reaction (Jaeger and Blanksma, Proc. K. Acad. Wetensch. Amsterdam, 1905, 8, 153). It melts at 105°.

3:4:6-Tribromo-o-xylene; from *4:6-dibromo-o-3-xylylene* by the Sandmeyer reaction (J. and B.). It melts at 86.5°.

Tetrabromo-o-xylene; from *o*-xylene and bromine (Jacobsen, Ber. 1884, 17, 2378), in presence of aluminium bromide (Blümlein, *ibid.* 2402). Long glistening needles, m.p. 262° (J.) or 254°–255° (B.), b.p. 374°–375° (B.); on oxidation at 170° with nitric acid (D 1.15) in the presence of bromine it yields tetrabromophthalic acid.

4-Chloro-5-bromo-o-xylene; by brominating 4-chloro-*o*-xylene in chloroform solution in the presence of iron, followed by distillation in a current of steam. Long colourless needles, m.p. 75° (Claus and Gronweg, J. pr. Chem. 1891, [2] 43, 252).

4:5-Dichloro-3-bromo-o-xylene; in a similar manner from *4:5-dichloro-o-xylene* (C. and G.). Colourless felted crystals, m.p. 90°.

3:5-Dichloro-4-bromo-o-xylene; together with dichlorotribromodimethyl-tetrahydrobenzene when *3:5-dichloro-1:1-dimethyl-Δ2:4-dihydrobenzene*, dissolved in a small amount of chloroform, is treated with about 2 mols. of bromine; by heating *3:5-dichloro-2:4:5-tribromo-1:1-dimethyl-Δ5-tetrahydrobenzene*; from *3:5-dichloro-o-4-xylylene* by the Sandmeyer reaction; together with *3:5-dichloro-4:6-dibromo-o-xylene* by brominating *3:5-dichloro-o-xylene* (Crossley, Chem. Soc. Trans. 1904, 85, 264). Felted needles, m.p. 100°, b.p. 170°–175°/30 mm., or 265°–270°/atm. It is volatile with steam and when heated with dilute nitric acid (D 1.15) at 180°–200° for 7 hours it yields *3:5-dinitro-phthalic acid* (C.).

3:5-Dichloro-6-bromo-o-xylene; together with *3:5-dichloro-o-xylene* by heating dichlorodibromodimethyltetrahydrobenzene, or by treating *3:5-dichloro-1:1-dimethyl-Δ2:4-dihydrobenzene* with 1 mol. of bromine and distilling the product, when the fraction, b.p. 220°–230°, consists of *3:5-dichloro-o-xylene*, whilst the intermediate fractions and that of b.p. 240°–250° contain *3:5-dichloro-6-bromo-o-xylene*; also together with other products (see *3:5-dichloro-o-xylene*) by oxidising dichlorodibromodimethyltetrahydrobenzene with potassium permanganate (C.). It forms long slender glistening needles, m.p. 42°. When brominated in presence of iron it yields the *4:6-dibromo-derivative*, whilst on heating with fuming nitric acid on the water-bath for 10 minutes it yields *3:5-dichloro-4:6-dinitro-o-xylene*. When heated with dilute nitric acid (D 1.15) at 180°–190° for 6 hours it yields *3:5-dichloro-6-nitro-o-toluic acid*.

3:5-Dichloro-4:6-dibromo-o-xylene; by brominating a warm solution of *3:5:6-trichloro-o-xylene* in chloroform in presence of iron (Hinkel, Chem. Soc. Trans. 1920, 117, 1296); by heating dichlorotribromodimethyltetrahydrobenzene with concentrated nitric acid (D 1.42) on the water-bath for 10 minutes; by brominating *3:5-dichloro-o-xylene*, or *3:5-dichloro-4- or 6-bromo-o-xylene* in presence of iron (C.). Slender glistening needles, m.p. 233°–233.5°, subliming in stout needles.

3:4:5-Trichloro-6-bromo-o-xylene; by brominating *3:4:5-trichloro-o-xylene* in presence

of iron (Hinkel, Chem. Soc. Trans. 1920, 117, 1296). Slender glistening needles, m.p. 226°.

For the iodo-derivatives of *o*-xylene, see Læser (Ber. 1884, 17, 1826), Klages and Liecke (J. pr. Chem. 1900, (2) 61, 307, 323), Edinger and Goldberg (Ber. 1900, 33, 2880), Datta and Chondhuri (J. Amer. Chem. Soc. 1916, 38, 1079), Knoll & Co. (D. R. P. 230172 of 1908), Finkelstein (Ber. 1910, 43, 1528).

The nitration of o-xylene. As the result of numerous experiments on the nitration of *o*-xylene under varied conditions, Crossley and Renouf (Chem. Soc. Trans. 1909, 95, 202), have arrived at the following conclusions. When fuming nitric acid alone is used and the nitration is effected below -4°, unchanged *o*-xylene is always recovered if less nitric acid is used than 6 times the weight of *o*-xylene. In all cases, however small an amount of nitric acid is used, dinitro-*o*-xylenes are obtained, and if the amount of nitric acid is increased to 15 times the weight of *o*-xylene, the amount of dinitro-*o*-xylene continually increases, but some mononitro-*o*-xylenes are always formed. When, however, *o*-xylene is nitrated with 10 times its weight of fuming nitric acid at 22°-25° an almost theoretical yield of dinitro-*o*-xylenes is produced. These results only hold good when the *o*-xylene is added to the nitric acid, for when nitric acid is added to *o*-xylene, a small amount of the latter is converted into mononitro-*o*-xylenes, together with a substance $C_{16}H_{17}O_2N$.

When the nitration is effected with nitric acid alone, about equal proportions of 3- and 4-nitro-*o*-xylene are produced, but with nitric and acetic acids, however, the proportion of the former to the latter is 1.5 : 1. Moreover, under these conditions no dinitro-*o*-xylenes are formed.

If the nitration is carried out with nitric and sulphuric acids below 0°, and the nitrating mixture is added to *o*-xylene, the proportion of 3-nitro-*o*-xylene obtained is about 8 times that of the 4-nitro-isomeride. If, on the other hand, *o*-xylene is added to the mixed acids, no mononitro-*o*-xylenes are produced, but a theoretical yield of dinitro-*o*-xylenes is obtained. Although this method gives rather better yields of dinitro-*o*-xylenes than when nitric acid is used alone, it is not to be recommended for their preparation, because a larger proportion of 4 : 5-dinitro-*o*-xylene, m.p. 115°, is formed, and this crystallises from sulphuric acid together with 3 : 4-dinitro-*o*-xylene, m.p. 82°, and the constituents of this mixture can be separated only by prolonged fractionation involving the use of large amounts of alcohol. To ensure the results described, it is not advisable to nitrate more than 50 grms. of *o*-xylene at one time.

ω-Nitro-o-xylene, o-tolyl-nitromethane; by dissolving *o*-nitro-*o*-xylyl phthalide in aqueous sodium hydroxide and precipitating with oxalic acid (Goldberg, Ber. 1900, 33, 2820); by boiling sodium-*o*-tolylisnitroacetoneitrile with aqueous sodium hydroxide (Wishlencus and Wren, Ber. 1905, 38, 502); by heating *o*-xylene with nitric acid (D 1075) in a sealed tube at 110° (Konowaloff, J. Russ. Phys. Chem. Soc. 1905, 37, 530). Oil (G.), or yellow oil, b.p. 137°-139°/23 mm. (W. and W.), or needles, m.p. 12°-14°, b.p. 145°-146°/23 mm.; D_4^{15} 1.423; n_D^{15} 1.54387 at 18° (K.). The corresponding iso-nitro derivative

melts at 61°-65° (K.). When kept, *o*-tolyl-nitromethane becomes red and deposits a crystalline substance which contains more nitrogen than the original compound and melts at 238°-242° (K.). The potassium derivative of *o*-tolyl-nitromethane, $C_8H_7KNO_2$, forms shining scales and its aqueous solution gives the following reactions: with copper sulphate, a dark green precipitate, soluble in ether or benzene with a red colour; with silver nitrate, a yellow precipitate, soluble in benzene, with a dark red colour; with mercuric chloride or stannic chloride, a white precipitate. Nitration with nitric acid (D 15) results in nuclear substitution. Its 5-bromo-*o*-toluic acid, m.p. 175°, and a liquid nitro-compound by the action of dilute nitric acid on bromo-*o*-xylene, melts at 65° (Konowaloff, &c., and J. Russ. Phys. Chem. Soc. 1904, 36, 537).

A nitro-*o*-tolyl-nitromethane, yellow leaflets, sintering at 170° and melting at 183°-185° (decomp.), has been obtained by Simonsen (Chem. Soc. Trans. 1913, 103, 1144), together with 3-nitro-*o*-xylene 4- and 5-sulphonic acids, and 4-nitro-*o*-xylene 5-sulphonic acid by gradually adding *o*-xylene 4-sulphonic acid to well-cooled fuming nitric acid (D 15) and then keeping the mixture at 30° for 2 days.

4-Nitro-*o*-tolyl-nitromethane,

forms crystals, m.p. 58°-59° (Konowaloff and Sentschikowski, J. Russ. Phys. Chem. Soc. 1904, 36, 462).

3-Nitro-*o*-xylene; in 90 p.c. yield together with 4-nitro-*o*-xylene by treating *o*-xylene with a mixture of nitric acid (D 1397) and sulphuric acid (D 184) below 0° and distilling the washed product with steam, or together with 4-nitro-*o*-xylene in the proportion of 2 : 1 by using nitric acid alone (Nölting and Forel, Ber. 1885, 18, 2668; Crossley and Renouf, Chem. Soc. Trans. 1909, 95, 202); from 3-nitro-*o*-4-xylylene by the diazo-reaction (Crossley and Wren, Chem. Soc. Trans. 1911, 99, 2341). Pale yellow refractive liquid, b.p. 240°/760 mm., solidifying on cooling to crystals, m.p. 15° (C. and W.); b.p. 250°/739 mm.; D_4^{15} 1.147 (N. and F.). When heated with nitric acid (D 115) in a sealed tube for 4 hours at 170°-180°, it yields 3-nitrophthalic acid, yellow transparent prisms, m.p. 217° (C. and R.; cf. Miller, Ann. 1881, 208, 240; Graeff, Ber. 1882, 15, 1127). When reduced with zinc dust and a dilute alcoholic solution of ammonium chloride it yields *o*-xylene-3-hydroxylaniline, white leaflets, m.p. 74° (Bamberger and Rising, Ann. 1901, 316, 257).

4-Nitro-*o*-xylene; see above; by nitrating 1 part of *o*-xylene with 8-10 parts of cold nitric acid (Jacobsen, Ber. 1884, 17, 159), or better with fuming nitric acid in presence of acetic acid at a temperature of 20°-25°. The yield of mononitro-derivatives obtained when *o*-xylene is nitrated with 8 times its weight of nitric acid is only half of that obtained when 6 times its weight of fuming nitric acid is used, and even in the latter case the yield is not as good as when nitric and acetic acids are used (C. and R.); from 5-nitro-*o*-4-xylylene by the diazo-reaction (Diepolder, Ber. 1909, 42, 2916). Long transparent glistening yellow prisms, m.p. 30°, b.p. 254°/748 mm. (slight decomp.), or 143°/21 mm.

(C. and R.); D¹⁰⁰ 1.139 (J.). On oxidation with dilute nitric acid it yields two nitrotoluic acids, and 4-nitrophthalic acid. When treated with caustic alkalis in the presence of air, it yields 4:4'-dinitro-2:2'-dimethyldibenzyl, lemon-yellow needles, m.p. 222°-224° (Green, Davies and Horsfall, Chem. Soc. Trans. 1907, 91, 2076). For electrolytic reduction, see Elbs and Kopp (Zeit. Elektrochem. 1898, 5, 108). When reduced with zinc dust and a dilute alcoholic solution of ammonium chloride 4-nitro-*o*-xylene yields *o*-xylene-4-hydroxylamine, white needles, m.p. 98°-101° (Bamberger and Rising, Ann. 1901, 316, 257).

3:4-Dinitro-*o*-xylene; from 3:4-dinitro-*o*-xylidine by the diazo-reaction (Crossley and Morrell, Chem. Soc. Trans. 1911, 99, 2345); by the action of fuming nitric acid on *o*-xylene at 22°-25°; also together with its isomerides by nitrating *o*-xylene or 4-nitro-*o*-xylene with fuming nitric acid or with mixed acids (C. and R.). Small silky needles, m.p. 82°. When heated in a sealed tube with nitric acid it yields 3:4-dinitrophthalic acid, m.p. 204°-205° (decomp.), and 3:4-dinitro-*o*-toluic acid, m.p. 182° (Warner, Chem. Soc. Proc. 1913, 29, 60).

3:6-Dinitro-*o*-xylene; by nitrating *o*-xylene; together with 4:6- and 3:4-dinitro-*o*-xylenes by nitrating 3-nitro-*o*-xylene with fuming nitric acid; as a by-product in the preparation of 3:4-dinitro-*o*-xylene (C. and R.; Crossley and Wren, Chem. Soc. Trans. 1911, 99, 2341). Sheaves of small needles, m.p. 89°-90°.

4:5-Dinitro-*o*-xylene; from 4:5-dinitro-*o*-xylidine by the diazo-reaction (C. and M.); together with 4:6- and 3:4-dinitro-*o*-xylene by nitrating 4-nitro-*o*-xylene in sulphuric acid solution with a mixture of nitric and sulphuric acids at the ordinary temperature and completing the reaction by heating for 10 minutes on the water-bath; also, but less conveniently, by nitrating 4-nitro-*o*-xylene with fuming nitric acid alone, the products being separated by fractional crystallisation from alcohol (Nölting and Thesmar, Ber. 1902, 35, 628), or by alternate crystallisation from sulphuric acid and alcohol (C. and R.). Long white glistening needles, m.p. 115°. It is more sparingly soluble in alcohol than 4:6-dinitro-*o*-xylene, and also differs from the latter in being readily converted into 5-nitro-4-amino-*o*-xylene by alcoholic ammonia at 150° (N. and T.).

4:6-Dinitro-*o*-xylene; see above; from 3:5-dinitro-*o*-xylidine by the diazo-reaction (Crossley and Morrell, Chem. Soc. Trans. 1911, 99, 2345); in largest quantity together with its isomerides by the action of fuming nitric acid on *o*-xylene at 22°-25° (C. and R.; cf. N. and T.); by heating 4:6-dinitro-*o*-tolylacetic acid (Borsche and Fiedler, Ber. 1913, 46, 2117). It crystallises from alcohol in faintly yellow, stout leafy needles, or long transparent needles, and from chloroform and light petroleum in stellar aggregates of long glistening needles, m.p. 75°-76° (C. and R.). It is reduced by ammonium sulphide to 6-nitro-*o*-4-xylidine, m.p. 74°-75°, and by tin and hydrochloric acid to the diamine (N. and T.). On oxidation with dilute nitric acid in a sealed tube it yields 3:5-dinitro-*o*-toluic acid, m.p. 206°, and 3:5-dinitrophthalic acid, m.p. 225° (W.).

3:4:5-Trinitro-*o*-xylene; together with

3:4:6-Trinitro-*o*-xylene by nitrating the mixture of the two isomeric dimethylcyclohexenes, obtained by eliminating 2 mols. of hydrogen bromide from 3:5-dibromo-1:1-dimethylcyclohexane, or by adding *o*-xylene to a cold mixture of nitric acid (D 1.5) and concentrated sulphuric acid and completing the nitration by heating the mixture on the water-bath for 15 hours; or the same mixture is obtained by the further nitration of 3:4- or 4:6-dinitro-*o*-xylene, whereas 4:5-dinitro-*o*-xylene on further nitration yields only 3:4:5-trinitro-*o*-xylene. It forms long colourless needles, m.p. 115° (Crossley and Renouf, Chem. Soc. Trans. 1908, 93, 629; 1909, 95, 202; cf. Harries and Antoni, Ann. 1903, 328, 88; Marquoyrol and Lorient, Bull. Soc. chim. 1920, [iv.] 27, 424).

3:4:6-Trinitro-*o*-xylene; see above; also as the sole product of the further nitration of 3:6-dinitro-*o*-xylene with fuming nitric acid and sulphuric acid (C. and R.). It forms faintly yellow glistening flat needles, m.p. 72°.

No tetranitro-derivatives are formed in the above nitrations. The 'dinitro-*o*-xylene,' m.p. 71°, obtained by Drossbach (Ber. 1886, 19, 2518), and erroneously considered by Nölting and Thesmar (l.c.) to be 4:6-dinitro-*o*-xylene, m.p. 75°-76°, has been shown by Crossley and Renouf (l.c.) to be actually 3:4:6-trinitro-*o*-xylene, m.p. 72°.

For the manufacture of trinitroxylene for use as a substitute for T.N.T. in bursting charges for high explosive shells, see Marshall (J. Ind. Eng. Chem. 1920, 12, 248).

When 50 grms. of commercial xylene, containing only the three isomerides, is nitrated with 500 grms. of mixed acids (2 parts of nitric acid, D 1.52 to 3 parts of sulphuric acid, D 1.84), 52 grms. of a solid trinitroxylene and 17 grms. of a yellow liquid nitroxylene are obtained. The presence of a small amount of dinitroxylens renders the product useless as an explosive, but by a second nitration a trinitroxylene capable of detonation by 0.15-0.2 gm. of silver azide is obtained in the form of white crystals, melting between 120° and 177° (Schweizer, Z. ges. Schiess- u. Sprengstoffw. 1919, 14, 24).

***o*-(2)-Chloro-4-nitro-*o*-xylene**; by treating a mixture of *p*-nitrotoluene and *s*-dichloromethyl-ether with fuming sulphuric acid (20 p.c. SO₃) and allowing the whole to stand (Stephen, Short and Gladding, Chem. Soc. Trans. 1920, 117, 510). Needles, m.p. 50°. On reduction with tin and hydrochloric acid it yields *o*-4-xylidine, and on oxidation with potassium permanganate it yields 4-nitrophthalic acid.

4-Chloro-5-nitro-*o*-xylene; by the action of nitric acid on 4-chloro-*o*-xylene (Claus and Groneweg, J. pr. Chem. 1891, (2) 43, 257). Needles, m.p. 73°.

3:5-Dichloro-4:6-dinitro-*o*-xylene; by nitrating 3:5-dichloro-*o*-xylene with fuming nitric acid and sulphuric acid for 10 minutes on the water-bath; or by dissolving 3:5-dichloro-6-bromo-*o*-xylene in fuming nitric acid and heating the solution on the water-bath for 20 minutes; by warming dichlorotribromodimethyltetrahydrobenzene with concentrated nitric acid (Crossley, Chem. Soc. Trans. 1904, 85, 264); by adding 3:5:6-trichloro-*o*-xylene to fuming nitric acid, and warming for a short time (Hinkel, Chem. Soc. Trans. 1920, 117,

1296). Attempts to obtain 3:5-dichloro-4:6-dinitro-*o*-xylene by chlorinating 4:6-dinitro-*o*-xylene failed (Crossley and Renouf, Chem. Soc. Trans. 1909, 95, 202). Faintly yellow glistening four-sided crystals, m.p. 175°–176° (C.).

4:5-Dichloro-3:6-dinitro-*o*-xylene; by nitrating 4:5-dichloro-*o*-xylene with fuming nitric acid and sulphuric acid (Claus and Berkefeld, J. pr. Chem. 1891, (2) 43, 583). Colourless transparent needles, m.p. 155°.

3:4:5-Trichloro-6-nitro-*o*-xylene; by the gradual addition of 3:4:5-trichloro-*o*-xylene to fuming nitric acid and warming on the water-bath for 20 minutes (Hinkel). Stout transparent crystals with a faint yellow tint, m.p. 149°.

3-Bromo-5-nitro-*o*-xylene; from 5-nitro-*o*-3-xylidine (Crossley and Bartlett, Chem. Soc. Trans. 1913, 103, 1297). Long colourless glistening needles, m.p. 101°.

Nitro-5-bromo-4-chloro-*o*-xylene; small colourless prisms, m.p. 223° (Claus and Groneweg, J. pr. Chem. 1891, (2) 43, 252).

3:5-Dichloro-4-bromo-6-nitro-*o*-xylene; by heating 3:5-dichloro-4-bromo-*o*-xylene for 20 minutes on the water-bath with fuming nitric acid (Crossley). Faintly yellow glistening needles, m.p. 175°–176.5°.

3-Nitro-4:5-dibromo-*o*-xylene; by nitrating 4:5-dibromo-*o*-xylene with fuming nitric acid in presence of glacial acetic acid (Crossley and Smith, Chem. Soc. Trans. 1913, 103, 989; Töhl, Ber. 1885, 18, 2651). Colourless needles, m.p. 141° (T.), or 143°–144° (C. and S.).

3:6-Dinitro-4:5-dibromo-*o*-xylene; together with the above compound by adding 4:5-dibromo-*o*-xylene to cold fuming nitric acid (Töhl). Small needles, m.p. about 250°.

o-Xylene 3-sulphinic acid; melts at 105° (Moschner, Ber. 1901, 34, 1257).

o-Xylene 4-sulphinic acid; by the action of zinc dust on *o*-xylene 4-sulphonylchloride (Jacobsen, Ber. 1877, 10, 1011); by treating *o*-xylene in carbon disulphide solution with sulphur dioxide in presence of aluminium chloride and hydrogen chloride at 0° (Knocvenagel and Kenner, Ber. 1908, 41, 3315). Large thin crystalline plates, m.p. 83° (J.), or 75° (K. and K.).

o-Xylene 3-sulphonic acid; by treating 6-chloro-*o*-xylene 3-sulphonic acid with sodium amalgam (Krüger, Ber. 1885, 18, 1760); by oxidising *o*-xylene 3-sulphinic acid (Moschner); by treating sodium 4:5-dibromo-*o*-xylene sulphionate with zinc dust and sodium hydroxide (Moody, Chem. Soc. Proc. 1892, 8, 213); by prolonged treatment of 3-bromo-*o*-xylene 6-sulphonic acid with sodium amalgam (Stallard, Chem. Soc. Trans. 1906, 89, 808). $\text{NaA}' + \text{H}_2\text{O}$, long flat plates. When heated at 115°–120° for 2 hours *o*-xylene 3-sulphonic acid is completely isomerised to *o*-xylene 4-sulphonic acid (Moody).

Chloride; prisms, m.p. 47° (Moody; Moschner), or 41.5°–43.5° (S.).

Sulphonamide; needles, m.p. 167°.

o-Xylene 4-sulphonic acid; by warming *o*-xylene with sulphuric acid (Jacobsen, Ber. 1877, 10, 1011; 1878, 11, 22). Long flat prisms or rectangular tables $+ 2\text{H}_2\text{O}$. Melts at 64° (Patterson, McMillan and Somerville, Chem. Soc. Trans. 1924, 126, 2489). $\text{NaA}' + 5\text{H}_2\text{O}$, long flat prisms, $\text{BaA}' + \text{H}_2\text{O}$, large rhombic plates. The barium salt may be obtained by oxidising

o-xylene 4-sulphinic acid with barium peroxide.

Chloride; large prismatic crystals, m.p. 51°–52°.

Amide; prisms, m.p. 144°.

The oxidation of *o*-xylene 4-sulphonic acid with permanganate yields two acids, and when treated at 40° with a solution of bromine in hydrochloric acid a mixture of 4-bromo-*o*-xylene, 4:5-dibromo-*o*-xylene and two bromo-*o*-xylene sulphonic acids is obtained (Kelbe and Stein, Ber. 1886, 19, 2137). *o*-Xylene 4-sulphonic acid on fusion with lead peroxide and potassium hydroxide gives phthalic acid in a yield of 70.5 p.c. (Graebe and Krafft, Ber. 1906, 39, 2507).

o-Xylene 4:6(?)-disulphonic acid; from *o*-xylene 4-sulphonic acid and chlorosulphonic acid at 150° (Pfannenstill, J. pr. Chem. 1892, (2) 46, 155). $\text{K}_2\text{A}'' + \text{H}_2\text{O}$, needles; $\text{BaA}'' + 3\text{H}_2\text{O}$; $\text{PbA}'' + 3\text{H}_2\text{O}$, large prisms.

Chloride; large prisms, m.p. 70°.

Amide; irregular crystals, m.p. 239°.

3-Chloro-*o*-xylene 6-sulphonic acid; small prismatic needles $+ 2\text{H}_2\text{O}$ (Claus and Bayer, Ann. 1893, 274, 304; Krüger, Ber. 1885, 18, 1755). $\text{NaA}' + \text{H}_2\text{O}$, large plates; $\text{BaA}' + \text{H}_2\text{O}$.

Amide; long prisms, m.p. 199° (K.). On treatment with sodium amalgam the free acid yields *o*-xylene 3-sulphonic acid (K.).

4-Chloro-*o*-xylene 5-sulphonic acid; colourless needles or nacreous plates $+ 5\text{H}_2\text{O}$ (C. and B.; K.). $\text{NaA}' + 5\text{H}_2\text{O}$, needles or flat prisms; KA' , vitreous needles; $\text{BaA}' + 4\text{H}_2\text{O}$, needles. The barium salt is more soluble than that of 3-chloro-*o*-xylene 6-sulphonic acid.

Amide; long needles, m.p. 207° (K.).

4-Bromo-*o*-xylene 5-sulphonic acid; by dissolving 4-bromo-*o*-xylene in slightly fuming sulphuric acid (Jacobsen, Ber. 1877, 10, 1011; 1878, 11, 22; 1884, 17, 2372; Stallard, Chem. Soc. Trans. 1906, 89, 808). Fibrous crystalline mass $+ x\text{H}_2\text{O}$. $\text{BaA}' + 3\text{H}_2\text{O}$, long hard prisms; $\text{NaA}' + 1\frac{1}{2}\text{H}_2\text{O}$, long slender needles; $\text{KA}' + \text{H}_2\text{O}$, thin vitreous prisms.

Amide; long hair-like needles, m.p. 213° (J.).

6- or 3-Bromo-*o*-xylene 4-sulphonic acid; together with 4:5-dibromo-*o*-xylene and 4-bromo-*o*-xylene by treating an aqueous solution of *o*-xylene 4-sulphonic acid at 40° with a solution of bromine in hydrochloric acid (Kelbe and Stein, Ber. 1886, 19, 2137); or better, by brominating barium *o*-xylene 4-sulphonic acid (Stallard). $\text{NaA}' + \frac{1}{2}\text{H}_2\text{O}$, needles; $\text{NaA}' + \text{H}_2\text{O}$, thin plates; KA' , stout needles (S.); BaA' , needles $+ 4\text{H}_2\text{O}$ (K. and S.).

Chloride; large six-sided plates, m.p. 85.5° (S.).

Amide; m.p. 191.5° (S.), or 186.5° (K. and S.).

When the sodium salt of the free sulphonic acid is dissolved in sulphuric acid and distilled with steam, 3-bromo-*o*-xylene is obtained (S.).

3-Bromo-*o*-xylene 6-sulphonic acid; together with the above compound by sulphonating 3-bromo-*o*-xylene (S.). BaA' , small plates or powder; $\text{NaA}' + \text{H}_2\text{O}$, thin plates; KA' , long flat needles.

Chloride; six-sided plates, m.p. 68.5°.

Amide; arborescent crystals, m.p. 195°.

The sodium salt of 3-bromo-*o*-xylene 6-sulphonic acid on prolonged treatment with

sodium amalgam yields sodium *o*-xylene 3-sulphonate.

3-Nitro-*o*-xylene 4-sulphonic acid; together with 3-nitro-*o*-xylene 5-sulphonic acid, 4-nitro-*o*-xylene 5-sulphonic acid and a dinitro-*o*-xylene by gradually adding *o*-xylene 4-sulphonic acid to well-cooled fuming nitric acid (D 1.5) and keeping the mixture for 6 hours at 0° and then at 30° for 2 days. The 3-nitro-*o*-xylene 5-sulphonic acid is isolated by means of its barium salt, and the remaining sulphonic acids are isolated as their sulphonamides (Simonsen, Chem. Soc. Trans. 1913, 103, 1144). Needles, BaA', glistening needles + H₂O.

Amide; large prismatic needles, m.p. 214°.

3-Nitro-*o*-xylene 5-sulphonic acid; hygroscopic slender needles (S.). BaA' + 3H₂O, glistening prismatic needles.

Chloride; large irregular glistening plates, m.p. 69°-70°.

Amide; fine hairlike needles, m.p. 180°.

4-Nitro-*o*-xylene 5-sulphonic acid; bayonet-shaped, somewhat hygroscopic needles (S.)

Amide; small hard prismatic needles, m.p. 157°-158°.

***m*-Xylene or isoxylene**; in lignite tar (Oehler, Zeitsch. angew. Chem. 1899, 12, 561) and in coal tar; together with a little *o*- and *p*-isomerides by the action of methyl chloride on toluene in presence of aluminium chloride (Ador and Rilliet, Ber. 1878, 11, 1627; Friedel and Crafts, Ann. Chim. Phys. 1884, (6) 1, 461); from *m*-iodotoluene (but not from *m*-bromotoluene) with methyl iodide and sodium (Wroblewsky, Ann. 1878, 192, 200); together with a little *p*-xylene by heating toluene with methyl iodide in the presence of iodine (Raymann and Preis, Ann. 1884, 223, 315); by distilling mesitylenic and xylylic acids with lime (Fittig, Ann. 1868, 148, 10; 1870, 156, 236; Zeit. für Chem. 1867, 526; Bull. Soc. chim. 1867, (2) 8, 268, 424); from pseudocumene or mesitylene by the action of aluminium chloride (Jacobsen, Ber. 1885, 18, 338). The fact that *m*-xylene is more slowly attacked by oxidising agents than are its *o*- and *p*-isomerides has been employed to obtain this hydrocarbon in a pure condition (Tawildarow, Zeit. für Chem. 1870, 418; Gundelach, Bull. Soc. chim. 1876, (2) 20, 43; Lako, Ann. 1876, 182, 30; Brückner, Ber. 1876, 9, 405; Bull. Soc. chim. 1876, (2) 26, 463).

For the separation of *m*-xylene from its *o*- and *p*-isomerides, see under *o*-xylene. According to a recent patent *m*-xylene may be separated from the mixture by means of 75 p.c. sulphuric acid in presence of *m*-xylene sulphonic acid. The *m*-xylene sulphonic acid thus produced is separated from the unchanged hydrocarbons and is subsequently desulphonated (Lepers, U.S. P. 1311848 of 1919).

Liquid, b.p. 139° (corr.), m.p. -50° (Fischer, Zeitsch. Elektrochem. 1910, 16, 161). It is stated by Pictet (Compt. rend. 1894, 119, 955) that *m*-xylene does not solidify at -100°. M.p. -54° to -53° (Colson, Ann. Chim. Phys. 1885, (6) 6, 128); b.p. 138.9°; D₄⁰ 0.8812 (Pinette, Ann. 1888, 243, 50); b.p. 139.2/759.2 mm.; D₄^{15.5} 0.8715, D₄^{19.2} 0.7572 (Schiff, Ann. 1883, 220, 92; cf. Neuback, Zeitsch. physikal. Chem. 1887, 1, 660); m.p. -45° (Altschul and Schneider, Zeitsch. physikal. Chem. 1895, 16, 24); b.p.

142.6°; D₄⁰ 0.8779, D₁₅¹⁵ 0.8691, D₂₅²⁵ 0.8625, D₄^{8.4} 0.87397 (Perkin, Chem. Soc. Trans. 1896, 1, 1241; 1900, 77, 278); D₄²⁰ 0.8655 (Brühl,

Ann. 1886, 235, 12; cf. von Hirsch, Ann. Phys. Chem. 1899, (2) 69, 456). Critical pressure and temperature (Altschul, Zeitsch. physikal. Chem. 1893, 11, 590); refractive power (Brühl; Landolt and Jahn, Zeitsch. physikal. Chem. 1892, 10, 303); capillarity constant (Schiff, Ann. 1884, 223, 104); electromagnetic property (Schönrock, Zeitsch. physikal. Chem. 1893, 11, 785); dielectric constant (Drude, *ibid.* 1897, 23, 309; Turner, *ibid.* 1901, 35, 427); other physical constants (von Auwers, Ann. 1919, 419, 92; Gladstone, Chem. Soc. Trans. 1891, 59, 290; Flusin, Compt. rend. 1898, 126, 1497); absorption spectrum in ultra-violet (Mies, Zeitsch. wiss. Photochem. 1910, 8, 287). It is not attacked by dilute nitric acid, and is only oxidised very slowly by potassium dichromate, forming isophthalic acid (Fittig and Velguth, Ann. 1868, 148, 11), but after conversion into the diethyl-ether, a colourless mobile oil, b.p. 246°-247°/712 mm., an almost theoretical yield of isophthalic acid is obtained on oxidation in a similar manner (Kipping, Chem. Soc. Trans. 1888, 53, 21). For other methods of oxidation in presence of catalysts, &c., see under *o*-Xylene.

When heated with phosphonium iodide it forms a hydrocarbon C₈H₁₄ (Bayer, Zeit. für Chem. (2) 4, 455).

The degradation of alkylbenzenes by means of anhydrous aluminium chloride was first noticed by Friedel and Crafts (Compt. rend. 1885, 100, 692). Anschütz (Ber. 1884, 17, 2816; 1885, 18, 657; Ann. 1886, 235, 182, 323) obtained toluene from *m*-xylene by heating the latter with anhydrous aluminium chloride. Jacobsen (Ber. 1885, 18, 338) obtained toluene from *m*-xylene in a similar manner, by boiling the mixture for 4 hours. On boiling with aluminium chloride the products are benzene, toluene, a little *p*-xylene, pseudocumene, mesitylene, and durene (Anschütz, Ann. 1886, 235, 182). Heise and Töhl (Ann. 1892, 270, 155), on passing dry hydrogen chloride through a mixture of 70 grms. of *m*-xylene and 20 p.c. of aluminium chloride heated for 6 hours at 100°, obtained only 2 grms. of hydrocarbon of lower boiling-point than *m*-xylene, together with benzene, mesitylene, some *p*-xylene and pseudocumene. Fischer and Niggemann (Ber. 1916, 49, 1475) found that for the most productive degradation of *m*-xylene to toluene, the reaction should be carried out at the boiling point of *m*-xylene for 2 hours in the presence of 2.4 p.c. of aluminium chloride. Under these conditions *m*-xylene yields approximately 12 p.c. of toluene together with benzene and polymethylated benzenes.

***m*-Xylene**, when treated with hydroxylamine hydrochloride in presence of aluminium chloride, yields 4-amino-*m*-xylene (Graebe, Ber. 1901, 34, 1778), and on heating with methyl iodide and iodine at 250° it yields pseudocumene, mesitylene, and a hydrocarbon C₁₀H₁₄ (Rayman and Preis, Ann. 1884, 223, 320). When treated with benzoyl peroxide *m*-xylene forms dixylylene (Lippman, Monatsch. 1886, 7, 528).

In the presence of aluminium chloride, *m*-xylene reacts with acetyl chloride to form

m-xylyl-4-methylketone (Verley, Bull. Soc. chim. 1897, (3) 17, 906); Claus and Gärtner, Ber. 1886, 19, 230; Ishzaka, Ber. 1914, 47, 2460), which, on oxidation with potassium permanganate, yields dimethylphenylglyoxylic acid, and on reduction with sodium amalgam yields *m*-xylyl-4-methylcarbinol (Claus, J. pr. Chem. 1890, (2) 41, 483). *m*-Xylyl-4-methylketone, on nitration with nitric acid (D 1.52) at temperatures below 30°, yields two mononitro-derivatives, but when the ketone is added slowly to a mixture of nitric acid (D 1.52) and sulphuric acid, a dinitro- and a dinitronitroso-ketone are obtained, the latter being formed in greater quantity at higher temperatures (Claus). *m*-Xylyl-4-methylketone when treated with sodium ethoxide and amyl nitrite yields xylylformoxime (Söderbaum, Ber. 1892, 25, 3459). *m*-Xylene condenses with bromoacetyl bromide in presence of aluminium chloride, forming *m*-xylyl-4-bromomethylketone (Jacobs and Heidelberger, J. Biol. Chem. 1915, 21, 455), whilst 5-methoxy-*m*-xylene with acetyl chloride yields 5-methoxy-*m*-xylyl-2-methylketone, and the xylenyl acetate in a similar manner yields 5-hydroxy-*m*-xylyl-2-methylketone (Auwers, Ber. 1915, 48, 90). *m*-Xylyl propyl ketone on oxidation with permanganate yields *o*-*p*-dimethylbenzoylformic acid (*m*-xylyl-glyoxylic acid), and on reduction in alkaline solution yields *m*-xylylpropylcarbinol; *m*-xylyl isopropyl ketone on oxidation with potassium permanganate also yields *m*-xylyl-glyoxylic acid. The ketones on heating with yellow ammonium sulphide, containing sulphur, yield the corresponding butyramides (Claus, J. pr. Chem. 1892, (2) 46, 474). *m*-Xylyl-3-chloromethylketone forms large white plates, m.p. 62°-63° (Kuncell, Ber. 1897, 30, 577; Ber. Deut. Pharm. Ges. 1912, 22, 242), whilst *m*-xylyl-4-bromoethylketone, prepared by gradually adding aluminium chloride to a mixture of α -bromopropionic chloride and *m*-xylene, is an oil, b.p. 160°-163°/20-25 mm. (Collet, Compt. rend. 1897, 125, 305). *m*-Xylyl-6-butylketone is obtained by the action of valeryl chloride on *m*-xylene in presence of aluminium chloride. It boils at 149°/16 mm., and forms an oxime, b.p. 184°-187°/21 mm., and a semi-carbazone, m.p. 188° (Layraud, Bull. Soc. chim. 1906, (3) 35, 223). 5-Butyl-*m*-xylyl-4-methylketone, obtained by slowly adding acetyl chloride to butylxylene and aluminium chloride, forms large plates, m.p. 48°, b.p. 265°, and does not react with hydroxylamine or phenylhydrazine. On oxidation with permanganate below 65° it yields butylxylyl-glyoxylic acid; when heated with aniline and *p*-toluidine by Bouveault's method butylxylylaldehyde is formed; on nitration the ketone yields a dinitro-derivative, which does not form an oxime or a phenylhydrazone, but yields a benzylidene-derivative, m.p. 140°, and a trichloroethylidene-derivative, m.p. 179° (Baur-Thurgau, Ber. 1898, 31, 1344; 1899, 32, 3647; 1900, 33, 2562). *m*-Xylene condenses with phthalic anhydride in presence of aluminium chloride forming *m*-xylene-phthalic acid (Meyer, Ber. 1882, 15, 636), with benzoyl chloride forming dimethylbenzophenone, and with phenylacetyl chloride forming dimethyl-desoxybenzoin (Söllicher, Ber. 1882, 15, 1680). Unsymm. *m*-xyleneoxyacetal boils at 273° and has D₂₀ 0.995; the hydrate melts at 62°. The

derived *o*-*p*-dimethylcoumarone is an oil, b.p. 221°-222°, D₁₅ 1.036, refractive index 1.5412 at 16°; with concentrated sulphuric acid it produces a violet coloration. It forms a picrate, m.p. 78°-79° (Stoermer and Schroeder, Ber. 1897, 30, 1700). Di-*m*-xylyl ethylene diketone C₂H₄[CO·C₆H₄(CH₃)₂]₂(CO·CH₃; CH₃=1:2:4) colourless needles, m.p. 129°, is obtained by the action of succinyl chloride on *m*-xylene in presence of aluminium chloride (Claus and Werner, Ber. 1887, 20, 1375).

When 4 mols. *m*-xylene, 1 mol. nickel carbonyl, and 4 mols. aluminium chloride are allowed to react for several days at the ordinary temperature, or when the mixture is heated for several hours in a sealed tube at 100°, a 20 p.c. yield of 2:4-dimethylbenzaldehyde is obtained. Under the latter conditions, 2:4:6:8-tetramethylantracene, identical with the product obtained by Anschütz (Ann. 1886, 235, 174) by the action of acetylene tetrabromide and aluminium chloride on *m*-xylene, is also formed (Dewar and Jones, Chem. Soc. Trans. 1904, 85, 217). 2:4-Dimethylbenzaldehyde has also been prepared by treating *m*-xylene in presence of aluminium chloride and cuprous chloride with carbon monoxide and hydrogen chloride (Gattermann and Koch, Ber. 1897, 30, 1622; 1898, 31, 1149; Gattermann, Ann. 1906, 347, 347), and from the phenylimide derived from *m*-xylyl-glyoxylic acid by boiling with dilute sulphuric acid (Bouveault, Compt. rend. 1896, 122, 1543). The tetramethylantracene obtained by Friedel and Crafts (Ann. Chim. Phys. 1887, (6) 11, 268) by the action of methylene chloride and aluminium chloride on *m*-xylene differs from the tetramethylantracene described above, and must be 1:3:6:8-tetramethylantracene.

m-Xylene is converted into *m*-tolualdehyde by Étard's reaction (Bornemann, Ber. 1884, 17, 1462). *m*-Xylylamide, lustrous needles, m.p. 180°, is formed when *m*-xylene and chloro-carbonylamide are heated gently; *m*-xylyl-anilide is prepared by heating a mixture of phenyl cyanate and *m*-xylene in presence of aluminium chloride (Leuchart, J. pr. Chem. 1890 (2), 41, 301).

When *m*-xylene is treated with mercury fulminate, sublimed aluminium chloride, aluminium hydroxide and hydrated aluminium chloride, a mixture of *aa*-*m*-xylylaldoxime, *m*-xylo-2-nitrile, m.p. 90°-91°, and *m*-xylo-4-nitrile, m.p. 24°, is formed; *m*-xylyl-4-aldoxime is separated from the nitriles by means of sodium hydroxide. The *syn*-form, m.p. 126°, is purified by precipitation from its ethereal solution with hydrochloric acid, and is converted into the *anti*-form, m.p. 85°-86°, by warming under water (Scholl and Kafer, Ber. 1903, 36, 322).

By the action of phosphorus chloride on *m*-xylene in presence of aluminium chloride, a mixture of *m*-xylyl-4- and 5(?)-chlorophosphines is obtained, the former being also formed by the action of phosphorus chloride on mercury dixylyl (Hg·CH₃; CH₃=4:1:3) at 230°-240°. The mixture on treatment with chlorine yields a mixture of the tetrachlorides, which with sulphur dioxide yields a mixture of oxy-chlorides (Weller, Ber. 1887, 20, 1718), whilst the chlorophosphines react with zinc-methyl to form xylylphosphine C₆H₄(CH₃)₂P(CH₃)₂H

b.p. 233°, and a little dimethylphosphine oxide (Conan, Ber. 1898, 31, 2919). The oxy-chlorides on prolonged boiling with water are converted into the corresponding *m*-xylylphosphinic acids (W.). *m*-Xylophosphonic acid,

(1:2:4:5) is obtained by oxidising pseudo-oumyl-phosphonic acid with potassium permanganate. It melts at 258°, and when heated above this temperature yields metaphosphoric acid and xylene carboxylic acid (Michaelis, Rothe, Ulster and Hecker, Ann. 1896, 293, 261). *m*-Xylene reacts with diphenylcarbamide in presence of aluminium chloride, forming *m*-xylyldiphenylamide, yellowish monoclinic prisms, m.p. 141°–142° (Lellmann and Bonhöffer).

When *m*-xylene is treated with ethyl bromide and aluminium chloride, both unsymm. and symm. ethyl *m*-xylenes are obtained and are separated by means of their sulphonamides. After these have been separated there remains an uncrystallisable sulphonamide from which, by heating with concentrated hydrochloric acid at 180°, 4-ethyl-*o*-xylene is obtained, molecular transformation having occurred (Töhl and Geyger, Ber. 1892, 25, 1533). *m*-Xylene, on treatment with aluminium chloride at 100°, yields a small amount of benzene, *p*-xylene and trimethyl-benzene, but for the greater part remains unchanged (Heise and Töhl, Ann. 1892, 270, 155). *m*-Xylene reacts with potassium thiocyanate, forming *m*-xylene thiocyanate, m.p. 160°–161° (Wheeler and Merriam, J. Amer. Chem. Soc. 1902, 24, 439). Aqua regia converts *m*-xylene into monochloro-, dichloro-, trichloro-, and tetrachloro-derivatives (Datta and Fernandes, J. Amer. Chem. Soc. 1916, 38, 1809).

When treated with 1 mol. of chlorosulphonic acid *m*-xylene yields chiefly *m*-xylene 4-sulphonic acid (amide, m.p. 137°), identical with that described by Jacobsen (Ber. 1877, 10, 1014) as 'erste metaxylyl-sulfonsäure' (Beckurts and Otto, Ber. 1878, 11, 2061). When *m*-mercury dixylyl is heated with boron chloride at 200° for 24 hours, *m*-xylylborochloride, colourless fuming liquid, b.p. 218°, is obtained, which is converted by pouring into water into *m*-xylylborooxide, white needles, m.p. 202°, and this yields *m*-xylylboric acid when boiled with water. *m*-Xylylborobromide is a colourless refractive liquid, b.p. 125°/15 mm.; D_4^{20} 1.57 (Michaelis, Thevenot, and Richter, Ann. 1901, 315, 19). Sulphuryl chloride reacts with *m*-xylene in presence of sunlight, forming a chloro-derivative, substituted in the side-chain, whilst in the absence of sunlight a good yield of 4-chloro-*m*-xylene is obtained. Similar results are obtained with sulphuryl chloride at 160°, but in the presence of aluminium chloride a sulphonyl chloride is obtained together with the above chloro-*m*-xylene (Töhl and Eberhard, Ber. 1893, 26, 2940). For arsenic derivatives of *m*-xylene, see Michael and Seemann (Ann. 1902, 320, 271), and for the hydrogenated derivatives of *m*-xylene, see Wallach (Ann. 1890, 258, 326); Tiemann and Semmler (Ber. 1895, 28, 2136); Verley (Bull. Soc. chim. 1897, (3) 17, 180); Wreden (Ber. 1872, 5, 608; 1873, 6, 1379; Ann. 1872, 163, 336; 1877, 187, 157); Putochin (J. Russ. Phys. Chem. Soc. 1884, 16, (2) 295); Lossen (Ann. 1884, 225, 110); Wallach (Ber. 1892, 25, 923);

Beilstein and Kurbatow (Ber. 1880, 13, 1820); Markownikoff and Spady (Ber. 1887, 20, 1850); Renard (Ann. Chim. Phys. 1884, (6) 1, 229); Aschan (Ber. 1891, 24, 2718); Schiff (Ber. 1880, 13, 1417; Gazz. chim. ital. 1880, 10, 320); Baeyer (Ann. 1870, 155, 272); Klages and Knoevenagel (Ber. 1894, 27, 3023); Ballo (Ann. 1879, 197, 322); Jakowkin (J. Russ. Phys. Chem. Soc. 1884, 16, (2) 294).

When sulphur chloride acts upon *m*-xylene in presence of the aluminium-mercury couple it is probable that dixylylene disulphide is first formed, and this yields *m*-xylyl hydrosulphide, or thioxyleneol when distilled (Cohen and Skirrow, Chem. Soc. Trans. 1899, 75, 890). The thioxyleneol obtained by Yssel (Zeit. für Chem. 1865, (2) 1, 360) by the action of zinc and sulphuric acid on xylene sulphonyl chloride is described as a liquid boiling at 213°. When treated with sulphur, *m*-xylene yields dimethyl-dibenzyl and *m*-dimethylstilbene (Aronheim and van Merop, Rec. trav. chim. 1903, 21, 448), and with triphenylmethyl, *m*-xylene forms the complex $\text{C}_6\text{H}_4(\text{CH}_2)_2 + 2[(\text{C}_6\text{H}_5)_3\text{C}]$ (Gomberg and Kone, Ber. 1905, 38, 1333).

5-Chloro-2:3-dihydro-*m*-xylene, oil, b.p. 78°–80°/15 mm., or 176°–178°/atm., is obtained by the action of phosphorus pentachloride on 3:5-dimethyl- Δ -ketotetrahydro-benzene (Klages and Knoevenagel, Ber. 1894, 27, 3019).

m-Xylylene cyanide on reduction with sodium and alcohol produces only about one-seventh of the normal reduction product, *m*-di- β -aminoethylbenzene $\text{C}_6\text{H}_4(\text{CH}_2\cdot\text{CH}_2\cdot\text{NH}_2)_2$, b.p. 165°–170°/20 mm., the chief product being a saturated secondary amine

b.p. 97°–98°/16 mm. The quaternary ammonium hydroxide, obtained from this base on treatment with methyl iodide, loses water and dimethylamine when distilled, forming an unsaturated hydrocarbon

b.p. 62°–63°/18 mm., D_4^{19} 0.900. Both these compounds yield isophthalic acid on oxidation. These reactions indicate the important fact that two meta-carbon atoms in a benzene ring may be connected not only by a nitrogen-containing chain, but also by a simple carbon chain (von Braun, Karpf and von Garn, Ber. 1920, 53, 98).

ω -Chloro-*m*-xylene, *m*-xylyl chloride,

by the action of chlorine on boiling *m*-xylene (Vollrath, Zeit. für Chem. 1866, 2, 488; Lauth and Grimaux, Bull. Soc. chim. 1867, (2) 7, 233; Ann. 1868, 145, 115; Gundelach, Bull. Soc. chim. 1876, (2) 26, 43; Compt. rend. 1876, 82, 1444); by the action of chlorine on *m*-xylene in sunlight (Radziewanowski and Schramm, Akad. Wiss. Krakau, 1898, 61); by the action of hydrogen chloride on *m*-xylyl alcohol

(Colson, Ann. Chim. Phys. 1885, (6) 6, 118). It boils at 196°; D_{20}^{20} 1.079.

ω-Dichloro-*m*-xylene, *m*-xylene chloride,

from the glycol $C_8H_6(CH_2OH)_2$, and hydrogen chloride (Colson, Bull. Soc. chim. 1885, (2) 43, 7; Compt. rend. 1884, 99, 42); by heating *m*-xylene with an equivalent amount of phosphorus pentachloride at 180°. The yield is not good, and to obtain a pure product it is necessary to hydrolyse it to the glycol, which is then treated as above (Colson and Gautier, Bull. Soc. chim. 1886, (2) 45, 6; Ann. Chim. Phys. 1885, (6) 6, 114; 1887, (6) 11, 23). *ω*-Dichloro-*o*-xylene is also obtained by the action of chlorine on *m*-xylene in sunlight (Radziewanowski and Schramm). It forms crystals, m.p. 34.2°, b.p. 253°, D_{20}^{20} 1.302.

Symm.-ω tetrachloro-m-xylene $C_8H_4(CHCl_2)_2$; by the action of chlorine on boiling *m*-xylene in presence of aluminium chloride (Bielecki, Bull. Acad. Sci. Cracow, 1908, 29).

It forms slender silky needles, m.p. 223°–223.5° (B.), whereas, according to Colson and Gautier (Bull. Soc. chim. 1886, (2) 45, 509; Compt. rend. 1886, 102, 689), it boils at 273°; D 1.536.

Hexachloro-m-xylene; by heating *m*-xylene with excess of phosphorus pentachloride in a sealed tube at 100° (Colson and Gautier, Compt. rend. 1886, 102, 689).

It boils at 286°, and is converted by dilute alkalis into complex acids containing chlorine. In this case, phosphorus pentachloride has attacked the nucleus, and, in this respect, *m*-xylene differs from its isomerides.

4-Chloro-m-xylene; from *m*-4-xylidine (Klages, Ber. 1896, 29, 310); by chlorinating *m*-xylene at 0° in presence of 5 p.c. of iodine (Jacobsen, Ber. 1885, 18, 1760; Vollrath, Zeit. für Chem. 1866, 488), or in chloroform solution in presence of iron (Claus and Burstert, J. pr. Chem. 1890, (2) 41, 532). The crude product may be purified by sulphonation (J.) or by fractional distillation (C. and B.).

Oil, which does not solidify at –20°, b.p. 186.5°/767 mm., D_{20}^{20} 1.0598 (J.); b.p. 180°–181° (uncorr., C. and B.), or 187–188/755 mm. (K.). On oxidation with chromic acid mixture it yields 6-chloro-*m*-toluic acid (J.).

4-Chloro-m-xylene is also obtained in good yield by the action of sulphuryl chloride on *m*-xylene in the absence of sunlight (Toll and Eberhard, Ber. 1893, 26, 2940).

5'-Chloro-2-m-xyloylbenzoic acid, m.p. 162°, obtained by the interaction of phthalic anhydride and *o*-chloro-*m*-xylene, on treatment with ammonium hydroxide in the presence of copper powder is converted into an amino-acid, m.p. 140° (decomp.), and subsequently into 1-amino-2:4-dimethylantraquinone, m.p. 293° (B. A. S. E., D. R. P. 234917 of 1910).

5-Chloro-m-xylene; from *m*-5-xylidine by the Sandmeyer reaction (Klages, Ber. 1896, 29, 310); from the bromide of 5-chloro-dihydro-*m*-xylene by the elimination of hydrogen bromide; by oxidising 5-chlorodihydro-*m*-xylene with cold potassium permanganate, potassium dichromate, or chromic acid in glacial acetic acid (Klages and Knoevenagel, Ber. 1894,

27, 3024; 1895, 28, 2044). Oil, b.p. 190°–191°/755 mm.

2:4-Dichloro-m-xylene; by heating *m*-xylene-2:4-disulphonylchloride with phosphorus pentachloride for 10 hours at 180° (Wischn, Ber. 1890, 23, 3113); together with the 4:6-isomeride by chlorinating cold *m*-xylene in presence of iodine (Koch, Ber. 1890, 23, 2318; cf. Hollemann, Zeit. für Chem. 1865, 554; Ann. 1867, 144, 268). Liquid, solidifying at –20°, b.p. 221.5°. When treated with methyl iodide and sodium it yields *v*-tetramethylbenzene.

4:5-Dichloro-m-xylene; from 4-chloro-*m*-5-xylidine by the Sandmeyer reaction (Klages). Oil, b.p. 231°–232°, readily volatile with steam.

4:6-Dichloro-m-xylene; see above; together with the mono- and trichloro-derivatives by chlorinating *m*-xylene in chloroform solution in the presence of iron (Claus and Burstert, J. pr. Chem. 1890, (2) 41, 552); together with the mono- and the tetrachloro-derivatives by treating *m*-xylene with *aqua regia* (Datta and Fernandes, J. Amer. Chem. Soc. 1916, 38, 1809).

Large pearly plates, which sublime, m.p. 68°, b.p. 222°–224°. On heating in a sealed tube with nitric acid (D 1.15) for 5–6 hours at 150° it yields 4:6-dichloro-3-methylbenzoic acid, whereas on heating with nitric acid (D 1.18) in a sealed tube at 220° for several hours, or with chromic acid, 4:6-dichloro-isophthalic acid is formed (C. and B.). Treatment with methyl iodide and sodium yields durenene, and when heated with concentrated sulphuric acid at 220° a 12 p.c. yield of 2:4-dichloro-*m*-xylene is obtained (Koch).

Trichloro-m-xylene (?); by chlorinating *m*-xylene in presence of iodine (Hollemann, Ann. 1867, 144, 270). Silky needles, m.p. 150°, b.p. 255°.

Trichloro-m-xylene; together with the mono-chloro-, 4:6-dichloro-, and the tetrachloro-derivatives by the action of *aqua regia* on *m*-xylene (Datta and Fernandes, J. Amer. Chem. Soc. 1916, 38, 1809); by chlorinating *m*-xylene in chloroform solution in presence of iron (C. and B.). Colourless, lustrous needles, m.p. 117°. It sublimes and on oxidation with nitric acid or chromic acid yields only trichloro-isophthalic acid. This trichloro-derivative is also formed by the method of Datta and Fernandes (l.c.).

Tetrachloro-m-xylene; see above. White brittle needles, m.p. 210° (C. and B.), or 212° (K.). Very resistant to oxidising agents.

ω-Bromo-m-xylene, *m*-xylyl bromide; by brominating boiling *m*-xylene (Radziszewski and Wispek, Ber. 1882, 15, 1743; 1885, 18, 1279; Atkinson and Thorpe, Chem. Soc. Trans. 1907, 91, 1687; Colson, Compt. rend. 1884, 99, 42; Bull. Soc. chim. 1885, (2) 43, 6); by the action of 1 mol. of bromine on cold *m*-xylene in the presence of indirect sunlight (Schramm, Ber. 1885, 18, 1277).

Colourless liquid, b.p. 215°/735 mm. (R. and W.); 212°–218° (C.); D_{20}^{20} 1.3711; b.p. 185°/340 mm. (Poppe, Ber. 1890, 23, 109); b.p. 212°–214° (A. and T.). When treated with potassium thiocyanate in dilute alcohol it yields *m*-xylyl thiocyanate, b.p. 170°/30 mm. (Strzelecka, Bull. Acad. Sci. Cracow, 1909, 731), and may be converted into *m*-tolylcarbinol, b.p. 216°–217.5°/758 mm.; D_{20}^{20} 1.028 (C.). When

treated with the sodium derivative of ethyl-acetoacetate it yields ethyl *m*-xylylacetoacetate, a yellowish oil, b.p. 195°/36 mm., which, when treated with nitrous acid under varied conditions, yields isonitroso-*m*-xylylacetic acid, $C_8H_4(CH_3)_2CH_2C(ONH)COOH$, and isonitroso-*m*-xylylacetone (Ryan, Ber. 1898, 31, 2129).

ω-*Dibromo-m-xylene*, *m*-xylene bromide $C_8H_4(CH_2Br)_2$; by brominating heated *m*-xylene (R. and W.; A. and T.; C.; Kipping, Chem. Soc. Trans. 1888, 53, 21; Pellegrin, Rec. trav. chim. 1899, 18, 458); by the action of bromine on *m*-xylene in direct sunlight (S.); from the glycol and hydrogen bromide.

Long prismatic, monoclinic needles, m.p. 77°; D_4^{20} 1.734; D^{20} 1.61 (C.); b.p. 135°–140°/20 mm. (P.).

On hydrolysis with aqueous potassium carbonate, *m*-xylene glycol, m.p. 45°–46° 2', is formed (C.), and with alkaline permanganate it yields isophthalic acid. With ethyl chloromalonate in presence of sodium ethylate it yields ethyl *m*-xylylenedichlorodimalonate (K.). With alcoholic potassium hydrosulphide it yields *m*-xylylene hydrosulphide, b.p. 157°/15 mm. (Kötz and Sevin, Ber. 1900, 33, 729); with potassium thiocyanate it yields *m*-xylylene thiocyanate, m.p. 60° (Strzelecka, Bull. Acad. Sci. Cracow, 1909, 731); by the action of bromobenzene in presence of sodium it yields diphenyl *m*-di-xylylene (?), $C_{12}H_{16}$, m.p. 131° 5', and di-*m*-phenylenediethene (?)

m.p. 191°, b.p. 260°/12 mm. (Pellegrin). *m*-Xylylene dibromide is converted into *m*-xylylene diiodide, m.p. 106°, when treated in acetone solution with sodium iodide (Finkelstein, Ber. 1910, 43, 1528; Knoll & Co., D. R. P. 230172 of 1908). For the action on primary, secondary, and tertiary amines, &c., see Halfpaap (Ber. 1903, 36, 1672). It reacts with ethyl acetoacetate in presence of sodium ethoxide to form ethyl *m*-xylylenedi-acetoacetate, a colourless viscous oil, which on treatment with 80 p.c. sulphuric acid is converted into ethyl hydrogen dimethylindacene dicarboxylate, m.p. 165°–166° (Ephraim, Ber. 1901, 34, 2779).

ω-ω-ω'-Tribromo-m-xylene, forms large prisms, m.p. 118° (A. and T.).

Symm. ω-tetrabromo-m-xylene $C_8H_4(CHBr)_2$; by the action of 200 c.c. of bromine on 100 grms. of *m*-xylene in direct sunlight at 90°–150° (Thiele, Gunther and Leopold, Ann. 1906, 347, 106). Colourless needles, or monoclinic plates, m.p. 107°. On treatment with concentrated sulphuric acid, or better, with potassium oxalate, *m*-phthalaldehyde is formed.

2-Bromo-m-xylene; by treating a hot solution of sodium *m*-xylene 2-sulphonate with a solution of bromine in hydrochloric acid (Jacobsen and Deike, Ber. 1887, 20, 904). Liquid at –10°, b.p. 206°. On treatment with methyl iodide and sodium, 1:2:3-trimethylbenzene is formed.

4-Bromo-m-xylene; by the action of bromine on cold *m*-xylene in the dark (Fittig, Ann. 1868, 147, 31; Schramm, Ber. 1885, 18, 1277), or in the presence of the aluminium-mercury couple (Cohen and Dakin, Chem. Soc. Trans. 1899, 75, 984); by the action of sulphur bromide and

nitric acid (D 1.4) on *m*-xylene in benzene solution (Edinger and Goldberg, Ber. 1900, 33, 2883). Oil, b.p. 203°–204° (F.), or 205° (E. and G.). When treated with the lead salt of thiophenol, it yields *as*-phenyl-*m*-xylyl sulphide $C_8H_4S-C_6H_5(CH_3)_2$ (Bourgeois, Ber. 1895, 28, 2312).

5-Bromo-m-xylene; from *m*-4-xylylidine by acetylation, bromination, hydrolysis, and elimination of the amino-group (Wroblewsky, Ann. 1878, 192, 215; Ber. 1876, 9, 497); from 5-bromo-*m*-4-xylylidine (E. Fischer and Windaus, Ber. 1900, 33, 1973). Liquid at –20°, b.p. 204°, D^{20} 1.362 (W.). When boiled for three-quarters of an hour with aluminium chloride and acetyl chloride in carbon disulphide solution, it is converted into 4-acetyl-5-bromo-*m*-xylene, b.p. 272°–276°, which, on oxidation with warm alkaline permanganate, yields 5-bromo-*m*-xylyl-4-glyoxylic acid (Noyes, Amer. Chem. J. 1898, 20, 789).

2:4-Dibromo-m-xylene; together with the 4:6-dibromo-isomeride by treating *m*-xylene with bromine (Jacobsen, Ber. 1888, 21, 2821); by heating 4:6-dibromo-*m*-xylene with sulphuric acid for a quarter of an hour at 240° (J.). Only liquid, solidifying on cooling to a hard crystalline mass, m.p. –8°, b.p. 269°/760 mm. It forms a 5:6-dinitro-derivative, almost colourless microscopic crystals, m.p. 191°, and on treatment with chlorosulphonic acid, 2:4-dibromo-*m*-xylene 6-sulphonic acid is obtained.

2:5-Dibromo-m-xylene; from 5-bromo-*m*-2-xylylidine (Blanksma, Rec. trav. chim. 1906, 25, 165). Colourless crystals, m.p. 28°.

4:5-Dibromo-m-xylene; from brominated *m*-xylylidine by the diazo-reaction (Wroblewsky, Ann. 1878, 192, 216); from 5:6-dibromo-*m*-4-xylylidine and 5-bromo-*m*-4-xylylidine (Jaeger and Blanksma, Rec. trav. chim. 1906, 25, 352; Proc. K. Akad. Wetensch. Amsterdam, 1905, 8, 153). Crystals, m.p. 11°, b.p. 256° (J. & G.); b.p. 252° (W.).

4:6-Dibromo-m-xylene; see above; from 6-bromo-*m*-4-xylylidine (Jaeger and Blanksma, Proc. K. Akad. Wetensch. Amsterdam, 1905, 8, 153; Rec. trav. chim. 1906, 25, 352); by brominating *m*-xylene (Fittig, Ann. 1867, 147, 25; 1870, 156, 236); by treating *m*-xylene with an excess of bromine in presence of iodine (Auwers and Traun, Ber. 1899, 32, 3312); by warming 6-bromo-*m*-xylene 4-sulphonic acid with bromine (Kelbe and Stein, Ber. 1886, 19, 2139). Crystals, m.p. 72°, b.p. 255°–256°, or m.p. 69° (J. and B.); b.p. 132°/12 mm. (Auwers and Traun). On heating with sulphuric acid at 240° it is converted into the 2:6-dibromo-isomeride. By the action of magnesium on an ethereal solution of 4:6-dibromo-*m*-xylene an organo-magnesium compound is obtained, which reacts readily with carbon dioxide, forming 5-bromo-2:4-dimethylbenzoic acid, and with chloral forming an alcohol, b.p. 197°–199°/15 mm. (Iocitsch, J. Russ. Phys. Chem. Soc. 1904, 36, 8).

2:4:5-Tribromo-m-xylene; from 4:5-dibromo-*m*-2-xylylidine by the Sandmeyer reaction (J. and B.). Colourless crystals, m.p. 87°.

2:4:6-Tribromo-m-xylene; from 2:4:6-dibromo-*m*-5-xylylidine by the elimination of the amino-group; from 4:6-dibromo-*m*-2-xylylidine and 2:6-dibromo-*m*-4-xylylidine, by

the Saadmeier reaction (J. and B.). Colourless prisms, m.p. 85°.

4:5:6-Tribromo-*m*-xylene; from 4:5:6-tribromo-*m*-2-xylydine and 5:6-dibromo-*m*-4-xylydine (J. and B.). Colourless crystals, m.p. 105°.

Tetrabromo-*m*-xylene; by keeping *m*-xylene in contact with an excess of bromine for a long time (Fittig and Bieher, Ann. 1870, 156, 235); by the action of bromine on *s*-tertiary butyl-*m*-xylene (Bodroux, Bull. Soc. chim. 1898, (3) 19, 889). Fine needles, m.p. 241° (F. and B.).

The bromination of *m*-xylene in presence of nitric acid yields a mixture of mono-, di-, and tetrabromo-*m*-xylenes (Datta and Chatterjee, J. Amer. Chem. Soc. 1916, 38, 2545).

4-Chloro-2-bromo-*m*-xylene; from bromo-*m*-xylydine by conversion into the hydrazine and boiling this with copper sulphate in hydrochloric acid solution (Noyes, Amer. Chem. J. 1898, 20, 789; Genz, Ber. 1870, 3, 225). White leaflets, m.p. 68°, b.p. 244°.

4:6-Dichloro-2:5-dibromo-*m*-xylene; by brominating an acetic acid solution of 4:6-dichloro-*m*-xylene in presence of iron (Claus and Runschke, J. pr. Chem. 1890, (2) 42, 125). Long silky needles which sublime, m.p. 230°.

2:4-Dichloro-5:6-dibromo-*m*-xylene; by the action of bromine on cold 2:4-dichloro-*m*-xylene (Koch, Ber. 1890, 23, 2318; Wischin, Ber. 1890, 23, 3113). Silky needles, m.p. 215°.

For the iodo-derivatives, *etc.*, of *m*-xylene, see Hammerich (Ber. 1890, 23, 1634); Töhl and Bauch (*ibid.* 1893, 26, 1105); Klages and Luecke (J. pr. Chem. 1900, (2) 61, 307, 324); Willgerodt and Howells (Ber. 1900, 33, 841); Noyes (Amer. Chem. J. 1898, 20, 789); Ortoleva (Gazz. chim. ital. 1900, 30, ii, 9); Edinger and Goldberg (Ber. 1900, 33, 2875); Willgerodt and Schmierer (Ber. 1905, 38, 1472); Datta and Choudhury (J. Amer. Chem. Soc. 1916, 38, 1079); Blankama (Rec. trav. chim. 1906, 25, 165; Proc. K. Akad. Wetensch. Amsterdam, 1905, 8, 70); Töhl and Bauch (Ber. 1893, 26, 1115).

ω -Nitro-*m*-xylene, *m*-toluene-nitromethane; by decomposing a solution of nitro-*m*-xylene-phthalide with hydrochloric acid (Heilmann, Ber. 1890, 23, 3165); by heating *m*-xylene with nitric acid (D 1-075), either in open or closed vessels (Konowaloff, J. Russ. Phys. Chem. Soc. 1899, 31, 254). Yellowish liquid, b.p. 140°/35 mm. (decomp.); D_0^{20} 1.137, D_0^{20} 1.1197 (K.). When kept in presence of calcium chloride, it yields *m*-toluic acid. The potassium salt of ω -nitro-*m*-xylene forms yellow leaflets, and the sodium, calcium, barium, and strontium salts are white stable powders (K.).

(c) or 2-Nitro-*m*-xylene; together with 4-nitro-*m*-xylene by nitrating *m*-xylene with sulphuric and nitric acids (Nölting and Forel, Bull. Soc. chim. 1884, (2) 42, 332, 338); from 2-nitro-*m*-4-xylydine by the diazo-reaction (Grevingk, Ber. 1884, 17, 2340); from 2:4:6-trinitro-*m*-xylene by reduction with ammonium sulphide and treatment of a boiling alcoholic solution of the diamine formed with nitrous fumes (Miolati and Lotti, Gazz. chim. ital. 1897, 27, i, 297; cf. Pechmann and Nold, Ber. 1898, 31, 560). Liquid, b.p. 225°/744 mm; D_0^{20} 1.112 (G.); b.p. 225° (N. and F.); m.p. 13° (Auwers and Pechmann, Ber. 1906, 41, 2337). When oxidised

with potassium permanganate in presence of magnesium sulphate, it yields 2-nitroisophthalic acid, and when boiled with nitric acid (D 1.4) *v*-dinitro-*m*-xylene, a substance,

and 2-nitro-*m*-toluic acid are formed (Nölting and Gachot, Ber. 1906, 39, 73). When reduced in alcoholic solution with zinc dust and ammonium chloride it yields *m*-xylene-2-hydroxylamine, white lustrous needles, m.p. 97°-98.5° (Bamberger and Rising, Ann. 1901, 316, 292; Pechmann and Nold, Ber. 1898, 31, 557), which is converted on oxidation into 2-nitroso-*m*-xylene, m.p. 144°-145° (P. and N.).

(i) or 4-Nitro-*m*-xylene; from dinitro-*m*-xylene, m.p. 93°, by partial reduction and elimination of the amino-group (Tawildarow, Zeitsch. fur Chem. 1870, 6, 418); by nitrating *m*-xylene (Harmsen, Ber. 1880, 13, 1658; N. and F.) or its dihydride (Wallach, Ann. 1898, 258, 330); from nitroxylidine, m.p. 123° (G.). Crystals, m.p. 2°, b.p. 237°-239°; D_0^{20} 1.126 (T.); b.p. 238° or 243°-244° (corr.), remaining liquid at -20° (Neubeck, Zeitsch. physikal. Chem. 1887, 1, 661; Harmsen). On reduction in alcoholic solution with zinc dust and ammonium chloride at about 60°-65° it yields *m*-4-xylydine, 4-azoxy-*m*-xylene, and *m*-xylene-4-hydroxylamine, glistening white plates, m.p. 64.5° (Bamberger and Brady, Ber. 1900, 33, 3642; cf. Bamberger, Ann. 1921, 424, 297; or m.p. 66° (Pechmann and Nold, Ber. 1898, 31, 560). For a further study of the reactions of *m*-xylyl-4-hydroxylamine, see Bamberger and collaborators (Ber. 1907, 40, 1893, 1906, 1918, 1932; 1900, 33, 3643).

(s) or 5-Nitro-*m*-xylene; from 5-nitro-*m*-4-xylydine by the elimination of the amino-group (Wroblewski, Ann. 1881, 207, 94; Bull. Soc. chim. 1880, (2) 34, 332). Large, flat needles, m.p. 74°-75°, b.p. 273°/739 mm. (Nölting and Forel, Ber. 1885, 18, 2678); m.p. 71°, b.p. 255° (Töhl, *ibid.* 360); m.p. 74° (Blankama, Rec. trav. chim. 1906, 25, 165; Proc. K. Akad. Wetensch. Amsterdam, 1905, 8, 70). When oxidised with potassium permanganate and acetic acid it yields 5-nitro-*m*-toluic acid. 5-Nitro-*m*-xylene is also formed together with 5-nitro-*m*-4-xylylnitroamine, by oxidising potassium-5-nitro-*m*-xyleneisodiazooxide with potassium ferricyanide (Bamberger and von Goldberger, Ber. 1920, 53, 2321).

ω -4-Dinitro-*m*-xylene; together with ω -6-dinitro-*m*-xylene by nitrating *o*-nitro-*m*-xylene at high temperatures with 70 p.c. nitric acid. It melts at 64° (Soc. Chim. Usines du Rhône, Eng. Pats. 6076 of 1911, 17985 of 1911; U.S. Pats. 1015496, 1015491; Fr. Pat. 426635; D. R. P. 239953 of 1910).

ω -6-Dinitro-*m*-xylene melts at 86.5°.

2:4-Dinitro-*m*-xylene; together with 4:6-dinitro-*m*-xylene, by nitrating *m*-xylene with a mixture of sulphuric acid (D 1.84), and nitric acid (D 1.498) at 5°. The yield of the 2:4-dinitro-compound diminishes the higher the temperature used in nitration (Grevingk, Ber. 1884, 17, 2423; cf. Errera and Maltose, Gazz. chim. ital. 1903, 33, ii, 277; cf. Nölting and Gachot, Ber. 1906, 39, 73; Morgan, Chem. Soc. Trans. 1902, 81, 86); by nitrating 2-nitro-*m*-xylene (Nölting, Braun and Thann, Ber. 1893,

34, 2243). The products are separated by crystallisation from alcohol or acetic acid in which 2:4-dinitro-*m*-xylene is more soluble than the 4:6-dinitro-isomeride. Glistening white plates, m.p. 83°-84° (N. B. and T.).

2:5-Dinitro-*m*-xylene; from 2:5-dinitro-*m*-4-xylydine by elimination of the amino-group (Blanksma, Rec. trav. chim. 1909, 28, 92; cf. Klages, Ber. 1896, 29, 310). Colourless needles, m.p. 101°, which become yellow on exposure to light (B.).

4:5-Dinitro-*m*-xylene; by nitrating 5-nitro-*m*-xylene with nitric acid (D 1.52) (Blanksma, Rec. trav. chim. 1906, 25, 165; Proc. K. Akad. Wetensch. Amsterdam, 1905, 8, 70); by the nitration of 5-nitroaceto-*m*-xylydide, followed by hydrolysis and removal of the amino-group (Blanksma, Rec. trav. chim. 1909, 28, 92). Klages (Ber. 1896, 29, 310) regarded this compound as the 2:5-dinitro-isomeride. It forms flat needles, m.p. 132° (B.; K.).

4:6-Dinitro-*m*-xylene; by nitrating *m*-xylene or its dihydride (Luhmann, Ann. 1867, 144, 274; Fittig and Velguth, Ann. 1868, 148, 5; Wallach, Ann. 1890, 258, 332; Errera and Maltese, Gazz. chim. ital. 1903, 33, ii, 277; Morgan, Chem. Soc. Trans. 1902, 81, 86); from 4:6-dinitro-*m*-5-xylydine (Blanksma, Rec. trav. chim. 1909, 28, 92; *ibid.* 1906, 25, 165; Proc. K. Akad. Wetensch. Amsterdam, 1905, 8, 70). Crystals, m.p. 93°. It is very resistant to oxidation and on treatment with nitric acid (D 1.15) at 155°-160° for 3 hours only $\frac{1}{2}$ is transformed into 4:6-dinitro-*m*-toluic acid, m.p. 171°-171.5° (Errera and Maltese, Gazz. chim. ital. 1903, 33, ii, 277). It condenses with 2 mols. of benzaldehyde at 190° in presence of a little piperidine to form 4:6-dinitro-1:3-distyrylbenzene, m.p. 186°, and a little 4:6-dinitro-3-methylstilbene, m.p. 145° (Borsche, Ann. 1912, 386, 351). On partial reduction it yields 6-nitro-*m*-4-xylydine (Morgan, Micklethwait and Couzens, Chem. Soc. Trans. 1906, 89, 1289; Blanksma, Rec. trav. chim. 1909, 28, 92).

5:6-Dinitro-*m*-xylene; from 5:6-dinitro-*m*-4-xylydine (Blanksma, Rec. trav. chim. 1906, 25, 165; Proc. K. Akad. Wetensch. Amsterdam, 1905, 8, 70).

2:5:6-Trinitro-*m*-xylene; by nitrating 2:5-dinitro-*m*-xylene (B.); together with 4:5:6-trinitro-*m*-xylene by treating 5-nitro-*m*-xylene with nitric acid (D 1.52) and sulphuric acid (B.). Triclinic crystals, m.p. 90°.

2:4:6-Trinitro-*m*-xylene; by nitrating *m*-xylene, its dihydride or tetrahydride (Luhmann; Grevingk; Tilden, Chem. Soc. Trans. 1884, 45, 416; Wallach, Ann. 1890, 258, 333; Knoevenagel, Ann. 1896, 289, 159; Bussonius and Eisenstuck, Ann. 1860, 114, 156; Molatti and Lotti, Gazz. chim. ital. 1897, 27, i, 293); by nitrating 4-iodo-6-nitro-*m*-xylene (B.). Large thick prismatic bipyramidal rhombic crystals, m.p. 182° (B.). It condenses with benzaldehyde in amyl alcoholic solution in the presence of a little piperidine to form 2:4:6-trinitro-1:3-distyrylbenzene (Borsche). When reduced with ammonium sulphide it yields a mixture of a monoamine and 6-nitro-4:6-diamino-*m*-xylene (M. and L.), but when reduced with stannous chloride it yields 2:4:6-triamino-*m*-xylene, white needles, decomposing between 140°-150° (Grevingk, Ber. 1896, 17, 2489).

4:5:6-Trinitro-*m*-xylene; by heating 4-iodo-5-nitro-*m*-xylene with nitric acid and sulphuric acid (B.); together with a little 2:5:6-trinitro-*m*-xylene by treating 5-nitro-*m*-xylene with nitric acid (D 1.52) and sulphuric acid (B.); by nitrating 4:5-dinitro-*m*-xylene with mixed acids (Blanksma, Rec. trav. chim. 1909, 28, 92). Long colourless monoclinic needles or rods, m.p. 125° (B.).

For nitroso-derivatives, etc., see Pechmann and Nold (Ber. 1898, 31, 560); Zincke and Schwarz (Ann. 1899, 307, 47); Zincke (J. pr. Chem. 1896, (2) 53, 340); Bamberger and Rising (Ann. 1901, 316, 292).

5-Chloro-2- (or 4-) nitro-*m*-xylene; together with other products by heating chlorodihydro-*m*-xylene with 30 p.c. nitric acid for 24 hours (Klages and Knoevenagel, Ber. 1895, 28, 2044). It is volatile with steam and melts at 48°-49°.

4-Chloro-6-nitro-*m*-xylene; from the corresponding nitroxyldine (Ahrens, Ann. 1892, 271, 17; Bamberger and Reber, Ber. 1913, 46, 787). Needles, m.p. 42°.

4-Chloro-5-nitro-*m*-xylene; from 5-nitro-*m*-4-xylydine (B.; Klages, Ber. 1896, 20, 310). Long colourless needles, m.p. 52°, b.p. 278° or 161°/20 mm.; volatile with steam.

4-Chloro-2:5-dinitro-*m*-xylene; from 2:5-dinitro-*m*-4-xylydine (Klages). Yellow crystals, m.p. 61°, b.p. 290°-291°.

4:6-Dichloro-2:5-dinitro-*m*-xylene; by nitrating 4:6-dichloro-*m*-xylene (Koch, Ber. 1890, 23, 2318; Claus and Runsche, J. pr. Chem. 1890, (2) 42, 110). Pale yellow cubes, m.p. 223° (C. and R.), or short hard prisms, m.p. 215° (K.).

4:6-Dichloro-2- (or 5-) nitro-*m*-xylene; by nitrating 4:6-dichloro-*m*-xylene in cold acetic acid solution (C. and R.). Long prisms, m.p. 118°-119°. An isomeride, m.p. 106°, is obtained under somewhat different conditions.

2:4-Dichloro-5:6-dinitro-*m*-xylene; by treating 2:4-dichloro-*m*-xylene with a warm mixture of nitric and sulphuric acids (K.). Pale yellow needles, m.p. 155°.

4-Chloro-2:5:6-trinitro-*m*-xylene; by heating 4-chloro-5-nitro-*m*-xylene with a mixture of sulphuric acid and nitric acid for 1 hour on the water-bath (Blanksma, Rec. trav. chim. 1906, 25, 165; Proc. K. Akad. Wetensch. Amsterdam, 1905, 8, 70). It melts at 165°.

5-Chloro-2:4:6-trinitro-*m*-xylene; by dissolving 5-chlorodihydro-*m*-xylene in ice-cold fuming nitric acid, keeping the mixture for some time at the ordinary temperature and then boiling with equal parts of fuming nitric acid and 15 p.c. fuming sulphuric acid for $\frac{1}{2}$ hour (Klages and Knoevenagel); by boiling 5-chloro-*m*-xylene with a mixture of nitric and sulphuric acids (Klages, Ber. 1896, 29, 310); by heating ethyl chlorotrinitrophenyleneacetic malonate with concentrated hydrochloric acid at 160°-170° in a sealed tube (Jackson and Smith, Amer. Chem. J. 1904, 32, 168). White needles, m.p. 218° (K.), or 215°-220° (J. and S.). When heated with ammonia it is converted into 2:4:6-trinitro-*m*-5-xylydine, m.p. 206°, and with aniline it forms 2:4:6-trinitro-5-phenylamino-*m*-xylene, m.p. 175°.

4-Bromo-2-nitro-*m*-xylene; by brominating 2-nitro-*m*-xylene in presence of iron powder (Anvers and Markovits, Ber. 1906, 41, 2332);

from 2-nitro-*m*-4-xylydine (Nölting, Braun and Thesmar, Ber. 1901, 34, 2242). Yellowish prisms or needles, m.p. 70°-71°.

4-Bromonitro-*m*-xylene; by dissolving 4-bromo-*m*-xylene in cold fuming nitric acid (Fittig, Ahrens and Mattheides, Ann. 1867, 147, 31). Liquid, b.p. 260°-265° with partial decomposition.

2-Bromo-4-nitro-*m*-xylene; from 4-nitro-*m*-2-xylydine (Nölting, Braun and Thesmar, Ber. 1901, 34, 2242). Bright yellow needles, m.p. 57°-58°.

4-Bromo-6-nitro-*m*-xylene; from 6-nitro-*m*-4-xylydine (Ahrens, Ann. 1892, 271, 17; Nölting, Braun and Thesmar, Ber. 1901, 34, 2242; Bamberger and Reber, Ber. 1913, 46, 787). Needles, m.p. 57°.

4-Bromo-5-nitro-*m*-xylene; from 5-nitro-*m*-4-xylydine (Blanksma). Colourless crystals, m.p. 56°. On nitration with nitric and sulphuric acids it yields 4-bromo-2 : 5 : 6-trinitro-*m*-xylene.

5-Bromo-6-nitro-*m*-xylene; from 5-bromo-6-nitro-*m*-4-xylydine by elimination of the amino-group (N., B. and T.). Faintly yellow needles, m.p. 39°-40°.

4-Bromo-2 : 6-dinitro-*m*-xylene; by the action of fuming nitric acid on 4-bromo-*m*-xylene (Lellmann and Just, Ber. 1891, 24, 2099). Small yellow needles, m.p. 89°.

4 : 6 : Dibromo-2-nitro-*m*-xylene; by nitrating 4 : 6-dibromo-*m*-xylene (Auwers and Traun, Ber. 1899, 32, 3309; F., A. and M.). Long needles, m.p. 108° (F., A. and M.), or 106° (A. and T.).

4 : 5 : Dibromo-2 : 6-dinitro-*m*-xylene; by nitrating 4 : 5-dibromo-*m*-xylene with nitric acid (D 152) and sulphuric acid (Blanksma, Rec. trav. chim. 1906, 25, 165; Jaeger and Blanksma, *ibid.* 352; Blanksma, Proc. K. Akad. Wetensch. Amsterdam, 1905, 8, 70, 153; cf. Jacobsen, Ber. 1888, 21, 2821). It melts at 193°.

4 : 6 : Dibromo-2 : 5-dinitro-*m*-xylene; by nitrating 4 : 6-dibromo-*m*-xylene with nitric acid in presence of sulphuric acid (J. and B.; cf. Jacobsen). It melts at 252°.

4-Bromo-2 : 5 : 6-trinitro-*m*-xylene; by nitrating 4-bromo-5-nitro-*m*-xylene in presence of sulphuric acid with nitric acid (D 152) (Blanksma). It melts at 183°.

5-Bromo-2 : 4 : 6-trinitro-*m*-xylene; by nitrating 5-bromo-*m*-xylene (Blanksma, Rec. trav. chim. 1906, 25, 373). Colourless crystals, m.p. 224°. When heated with *m*-xylydine in alcoholic solution it is converted into 2 : 4 : 6-trinitro-di-1 : 3 : 5-xylylamine, which, on nitration, yields *s*-hexanitro-di-1 : 3 : 5-xylylamine, m.p. 222° (B.).

m-Xylene 4-sulphinic acid; from *m*-xylene 4-sulphonyl chloride (Jacobsen, Ber. 1877, 10, 1011); by the action of sulphur dioxide on the diazoesulphate of *m*-4-xylydine in excess of sulphuric acid, followed by the gradual addition of copper powder, until the evolution of nitrogen ceases (Gattermann, Ber. 1899, 32, 1136); by the action of sulphur dioxide on *m*-xylene in presence of hydrogen chloride, and aluminium chloride (Knoevenagel and Kenner, Ber. 1908, 41, 3315). Long colourless needles, m.p. 77°-78° (G.). On reduction it yields *m*-xylylmercaptan, b.p. 207°-208° (G.), and with alkyl haloids, sodium *m*-xylene 4-sulphinate forms alkyl xylyl sulphones (Tröger, Budde and Hill,

m-Xylene 5-sulphinic acid; from *s*-*m*-xylydine by Gattermann's method (Moschner, Ber. 1901, 34, 1257). It melts at 75°-76°.

(β)-*m*-xylene 2-sulphonic acid; by reducing dibromo-*m*-xylene 2-sulphonic acid with zinc dust and sodium hydroxide (Moody, Chem. Soc. Proc. 1888, 4, 77); by reducing 5-chloro-*m*-xylene 2-sulphonic acid with sodium amalgam (Klages, Ber. 1896, 29, 310); together with a larger quantity of the 4-sulphonic acid, by dissolving *m*-xylene in fuming sulphuric acid. It remains in the acid liquor after precipitating the 4-isomeride with water (Jacobsen, Ann. 1876, 184, 188; Ber. 1877, 10, 1015; 1878, 11, 17; cf. Beckurts and Otto, Ber. 1878, 11, 2061). Moody states that the sulphonation of pure *m*-xylene yields only one sulphonic acid, viz. *m*-xylene 4-sulphonic acid. KA', needles (J.); BaA', microscopic needles (J.); the potassium salt when heated with sodium formate yields an acid, C₈H₁₀O₂, m.p. 99° (J.).

m-Xylene 2-sulphonic acid is readily isomerised into *m*-xylene 4-sulphonic acid by heating at 100° (M.).

Chloride; oil (J.), or prisms, m.p. 30° (M.).

Amide; slender brittle needles, m.p. 113° (M.; cf. Jacobsen and Weinberg, Ber. 1878, 11, 1534), or m.p. 95°-96° (J.; K.). Moody states that Jacobsen's sulphonamide, m.p. 95°-96°, is not a pure derivative of *m*-xylene, but is a mixture containing a considerable quantity of *p*-xylene sulphonamide.

(α)-*m*-xylene 4-sulphonic acid; see above; by reducing sodium diiodo-*m*-xylene sulphonate with zinc dust and ammonia (Töhl and Bauch, Ber. 1893, 26, 1105). Long flat prisms + 2H₂O. Melts at 62°. The calcium salt is less soluble in hot than in cold water (Patterson, McMillan and Somerville, Chem. Soc. Trans. 1924, 125, 2489). NaA', small anhydrous scales (J.); BaA', small rhombic anhydrous plates (J.), or anorthic (?) tables + 1H₂O; ZnA', + 9H₂O; CuA', + 6H₂O.

Chloride; large prismatic crystals, m.p. 34° (J.) or 32° (Schreinmakers, Rec. trav. chim. 1897, 16, 411).

Amide; m.p. 137° (J.; cf. Töhl and Eberhard, Ber. 1893, 26, 2940; Beckurts and Otto, *l.c.*); methylamide, m.p. 43°; dimethylamide, m.p. 35° (Schreinmakers). Chloroacetamide reacts with sodium *m*-xylene 4-sulphonate forming *m*-xylene 4-sulphonacetamide, m.p. 149°, and with chloroacetonitrile forming *m*-xylene 4-sulphonacetoneitrile, m.p. 79°-80°. The latter on treatment with alcoholic ammonia and hydrogen sulphide is converted into *m*-xylene-4-sulphonthioacetamide, m.p. 118° (Tröger, Hill and Volkner, J. pr. Chem. 1904, (2) 70, 315; 1905, (2) 71, 201, 236). *m*-Xylene 4-sulphonic acid condenses with *p*-nitroaniline in pyridine solution forming *m*-xylene 4-sulphonyl-*p*-nitroaniline, which, when freed from benzene of crystallisation, melts at 117°-119°. On reduction, the latter yields the corresponding diamine, m.p. 156°-157°, the diazonium chloride of which yields *m*-xylene 4-sulphonyl-*p*-phenylenediazoamide on treatment with sodium acetate (Morgan and Micklethwait, Chem. Soc. Trans. 1906, 17, 1302). *m*-Xylene 4-sulphonic acid, when treated at about 40° with a solution of bromine

in hydrochloric acid, yields monobromo-*m*-xylene, 4:6-dibromo-*m*-xylene, and an acid m.p. 130° (Kelbe and Stein, Ber. 1886, 19, 2137). When fused with lead peroxide and potassium hydroxide it is oxidised with difficulty, forming isophthalic acid, and traces of benzoic and *m*-toluic acids (Graebe and Krafft, Ber. 1906, 39 2507).

m-Xylene 5-sulphonic acid; by diazotising potassium *m*-4-xylylene 5-sulphonate and boiling with alcohol, or by means of the hydrazine (Armstrong and Wilson, Chem. Soc. Proc. 1900 16, 229). The acid forms thin flat needles $\text{KA}' + \frac{1}{2}\text{H}_2\text{O}$; $\text{BaA}'_2 + 2\text{H}_2\text{O}$, colourless leaflet (A. and W.).

Chloride, needles or massive crystals, m.p. 94° (A. and W.), or 89°–90° (Moschner, Ber. 1901, 34, 1257); *bromide*, m.p. 92°–93° (A. and W.).

Sulphonamide, colourless flakes or very fine needles, m.p. 134° (A. and W.), or 135° (M.; Jungmann, Ber. 1902, 35, 3747). *Anilide*, large monosymmetric crystals, m.p. 119; *p*-toluidide, monosymmetric crystals, m.p. 121°–122° (A. and W.).

m-Xylene 4:6-disulphonic acid, formerly believed to be the 2:4-disulphonic acid but shown to be the 4:6-disulphonic acid by Pollak and Lustig (Ann. 1923, 433, 191; Pollak and Rudich, Monatsh. 1922, 43, 206); by heating 1 part of *m*-xylene with 4 parts of fuming sulphuric acid at 150° (Wischn, Ber. 1894, 23, 3113; Pollak and Schädler, Monatsh. 1911, 39, 129); by heating *m*-xylene 4-sulphonic acid with chlorosulphonic acid at 150° (Pfannenstill, J. pr. Chem. 1892, (2) 46, 152); from crude xylylene by sulphonation, diazotisation, conversion into thioxylenol sulphonic acid, and oxidation of the latter (Pfannenstill, Ber. 1894, 27, 1888). Deliquescent needles, $(\text{NH}_4)_2\text{A}'$, tab.; NaHA'' (W.), $+3\text{H}_2\text{O}$ (P); $\text{K}_2\text{A}'' + 2\text{H}_2\text{O}$; $\text{BaA}'' + 3\text{H}_2\text{O}$, needles; $\text{PbA}'' + 3\text{H}_2\text{O}$; Cu'' , gummy mass.

Diethyl-ester; leaflets (P.).

Chloride; conveniently by heating *m*-xylene or *m*-xylene 4-sulphonic acid (or its sodium salt) with seven times its weight of chlorosulphonic acid at 150°–160° (Pollak and Lustig). Needles, m.p. 129° (W.; P.), 130° (P. and L.) or 131° (Pfannenstill, Ber. 1894, 27, ref. 888).

Amide; glistening needles, m.p. 249° (W.; L.); *ethylamide*, needles, m.p. 135° (W.).

The 4:6-disulphonyl chloride, on reduction with tin and hydrochloric acid, yields 4:6-dithiol-*m*-xylene, m.p. 123°–125°, which reacts with chloroacetic acid and ethyl chloroformate, forming *m*-xylene-4:6-dithiolacetic acid, m.p. 185°–189°, and 4:6-diethylthiocarbonat-*m*-xylene, m.p. 61°–63°.

m-Xylene 2:5-disulphonic acid, or possibly *m*-xylene 2:4-disulphonic acid (Pollak and Lustig), together with *m*-xylene 4:6-disulphonic acid by sulphonating *m*-xylene (Pollak and Schädler); in small quantity, together with the 4:6-disulphonic acid, by heating barium *m*-xylene 2-sulphonate with chlorosulphonic acid at 150° (P.). Needles. The potassium, barium and lead salts are crystalline and readily soluble in water.

Chloride; brown viscous oil.

Amide; m.p. 210° (P.).

The 2:5-disulphonyl chloride gives rise to

2:5-dithiol-*m*-xylene, b.p. 142°–144°/9 mm., and from this *m*-xylene-2:5-dithiolacetic acid, m.p. 158°–161°, is obtained (Pollak and Schädler), 5-Chloro-*m*-xylene 2-sulphonic acid; together with a small quantity of its anhydride,

by sulphonating 5-chloro-*m*-xylene with 10 times its weight of fuming sulphuric acid (15 p.c. SO_3) at 30°–40° (Klages, Ber. 1896, 29, 310; Klages and Knoevenagel, Ber. 1894, 27, 3019). Colourless crystals, m.p. 52°.

Chloride; large rhombic crystals, m.p. 56°–58° (K.).

Amide; colourless needles, m.p. 192° (K.).

4-Chloro-*m*-xylene 6-sulphonic acid; by sulphonating 4-chloro-*m*-xylene (Gundelach, Bull. Soc. chim. 1877, (2) 28, 343. On reduction with sodium amalgam it yields *m*-xylene 4-sulphonic acid (Jacobsen, Ber. 1885, 18, 1762). $\text{NaA}' + \text{H}_2\text{O}$, long needles; $\text{KA}' + \text{H}_2\text{O}$, needles.

Amide; vitreous prisms, m.p. 195° (J.).

2:4-Dichloro-*m*-xylene 6-sulphonic acid; by treating 2:4-dichloro-*m*-xylene with chlorosulphonic acid (Koch, Ber. 1890, 23, 2318).

Amide; small white plates, melting with decomposition above 300°.

4:6-Dichloro-*m*-xylene 2-sulphonic acid; in a similar manner to the above isomeride from 4:6-dichloro-*m*-xylene (K.).

Amide; small plates, melting with decomposition above 250°.

4-Chloro-*m*-xylene 2:6-disulphonic acid; by sulphonating 4-chloro-*m*-xylene with fuming sulphuric acid (Wischn, Ber. 1890, 23, 3117).

Chloride; white needles, m.p. 155°.

Amide; silky needles, m.p. 270°. The free acid on fusion with potassium hydroxide yields the corresponding dihydroxy-derivative, white needles, which sublime, m.p. 106°, and produce an intense violet coloration with ferric chloride.

6-Bromo-*m*-xylene 2-sulphonic acid; by reducing dibromo-*m*-xylene sulphonamide with sodium amalgam (Jacobsen and Weinberg, Ber. 1878, 11, 1535).

Amide; long needles, m.p. 161°.

6-Bromo-*m*-xylene 4-sulphonic acid; by brominating barium *m*-xylene 4-sulphonate, or by sulphonating 6-bromo-*m*-xylene with fuming sulphuric acid (Weinberg, Ber. 1878, 11, 1062) from *m*-4-xylylene 6-sulphonic acid by the diazo-reaction (Sartig, Ann. 1885, 230, 335; Nölting and Kohn, Ber. 1886, 19, 139; Limpricht, Ber. 1885, 18, 2188; Moody, Chem. Soc. Proc. 1891, 7, 189). Leaflets or needles, which do not melt at 270° (M.), readily soluble in water.

$\text{NaA}' + \text{H}_2\text{O}$; $\text{BaA}' + \text{H}_2\text{O}$, scales;

$\text{ZnA}' + 9\text{H}_2\text{O}$; $\text{CuA}' + 7\text{H}_2\text{O}$.

Chloride; oblique prisms, m.p. 62°–63° (M.), or 61° (W.; L.).

Amide; small rhombic prisms, m.p. 194° (W.; L.), or 189°–190° (N. and K.; M.); *anilide*, m.p. 152° (Jungmann, Ber. 1902, 35, 3747).

4-Bromo-*m*-xylene 5-sulphonic acid; from *m*-4-xylylene 5-sulphonic acid by the Sandmeyer reaction (Jungmann). Colourless needles.

$\text{NaA}' + \text{H}_2\text{O}$; BaA' , anhydrous.

Chloride; pale yellow plates, m.p. 75°.

Amide; colourless prisms, m.p. 158°, converted by reduction with sodium amalgam and alcohol into *m*-xylene 5-sulphonamide.

Anilide; colourless needles, m.p. 179°.

2:4-Dibromo-*m*-xylene 6-sulphonic acid; by treating 2,4-dibromo-*m*-xylene with chlorosulphonic acid (Jacobsen, Ber. 1888, 21, 2825) $\text{NaA}' + \text{H}_2\text{O}$, needles, converted on reduction with zinc dust and ammonia into sodium *m*-xylene 4-sulphonate; $\text{KA}' + \text{H}_2\text{O}$, leaflets BaA'_2 , small prisms.

Amide; small prisms, melting with decomposition about 300° (J.).

4:6-Dibromo-*m*-xylene 2-sulphonic acid; by adding water to a solution of 4:6-dibromo-*m*-xylene in fuming sulphuric acid (Jacobsen and Weinberg). Leaflets (anhydrous), melting with decomposition at 165° ; converted by reduction with sodium amalgam into 6-bromo-*m*-xylene 2-sulphonic acid and *m*-xylene 2-sulphonic acid $\text{NaA}' + 2\text{H}_2\text{O}$, colourless pearly plates; BaA'_2 crystals.

Chloride; colourless rhombic plates, m.p. 107° .

Amide; woolly needles, melting at 220° and decomposing at 230° (J. and W.).

4-Bromo-*m*-xylene 2:6-disulphonic acid; by sulphonating 4-bromo-*m*-xylene (Wischn, Ber. 1890, 23, 3113). On reduction with zinc dust and ammonia it yields *m*-xylene 2:4-disulphonic acid.

Chloride; long white needles, m.p. 160° , converted on fusion with potassium hydroxide into 4-bromo-2:6-dihydroxy-*m*-xylene, needles, which sublime, m.p. 126° .

Amide; needles, m.p. 265° (Wischn).

2-Nitro-*m*-xylene 4-sulphonic acid; together with 5-nitro- and 6-nitro-*m*-xylene 4-sulphonic acids by nitrating *m*-xylene 4-sulphonic acid (Claus and Schmidt, Ber. 1886, 19, 1418). Small plates $+ \text{H}_2\text{O}$, m.p. 144° (anhydrous). $\text{NaA}' + \text{H}_2\text{O}$, colourless plates; $\text{KA}' + \frac{1}{2}\text{H}_2\text{O}$, small colourless leaflets; BaA'_2 , large plates; $\text{CuA}'_2 + 2\text{H}_2\text{O}$, blue tables; $\text{AgA}' + \frac{1}{2}\text{H}_2\text{O}$, small white leaflets.

Chloride; long colourless prisms, m.p. 96° (C. and S.).

Amide; colourless needles or prisms, m.p. 172° (C. and S.).

5-Nitro-*m*-xylene 4-sulphonic acid; see above; formed only in small quantity. Small nodules of colourless plates, m.p. 95° – 100° . The salts are very soluble in water, and the much greater solubility of the barium salt is utilised for the separation of this acid from its isomerides. $\text{NaA}' + \text{H}_2\text{O}$, small needles; KA' , leaflets; $\text{BaA}'_2 + 1\frac{1}{2}\text{H}_2\text{O}$; $\text{CaA}'_2 + 6\text{H}_2\text{O}$, small white needles; $\text{CuA}'_2 + 6\text{H}_2\text{O}$, bluish-green needles; $\text{AgA}' + \text{H}_2\text{O}$, small pale yellow prisms.

Chloride; colourless plates, m.p. 97° (C. and S.).

Amide; small colourless needles, m.p. 108° (C. and S.).

6-Nitro-*m*-xylene 4-sulphonic acid; by nitrating *m*-xylene 4-sulphonic acid (C. and S.; Pollak and Lustig, Ann. 1923, 433, 191; Karlsake and Bond, J. Amer. Chem. Soc. 1909, 31, 405; Riessen, Ber. 1885, 18, 2174; Limpriht, *ibid.* 2172, 2191); by sulphonating nitro-*m*-xylene at 70° (Harmen, Ber. 1890, 13, 1558). Long colourless needles, m.p. 122° (H.), or long thick prisms, m.p. 132° (B.). KA' , yellow needles (L.); $\text{NaA}' + 2\text{H}_2\text{O}$, yellow needles (L.), or $+ \text{H}_2\text{O}$ (H.); $\text{BaA}'_2 + 3\frac{1}{2}\text{H}_2\text{O}$, long white needles (L.); M octagonal plates (H.); $\text{CaA}'_2 + 6\text{H}_2\text{O}$, pale yellow prisms H.; $\text{CuA}'_2 + 6\text{H}_2\text{O}$,

green tables (C. and S.); AgA' , fine white needles (C. and S.).

Chloride; m.p. 98° (L.; R.).

Amide; needles, m.p. 179° (L.), or 187° (C. and S.).

When oxidised with cold alkaline permanganate, potassium 6-nitro-*m*-xylene 4-sulphonate yields 6-nitro-3-methyl-4-sulpho-benzoic acid monopotassium salt, 4-nitro-5-methyl-2-sulpho-benzoic acid dipotassium salt, and 6-nitro-4-sulpho isophthalic acid monopotassium salt (K. and B.).

2:6-Dinitro-*m*-xylene 4-sulphonic acid; by prolonged heating of *m*-xylene 4-sulphonic acid with concentrated nitric acid (Limpriht), or by the action of cold nitric acid (D 152) on *m*-xylene 4-sulphonic acid (Pollak and Lustig, Ann. 1923, 433, 191); by nitrating 2- and 6-nitro-*m*-xylene 4-sulphonic acids (Claus and Schmidt). Crystals $+ 2\text{H}_2\text{O}$ (L.). $\text{NaA}' + \text{H}_2\text{O}$, leaflets (C. and S.); KA' , slender prisms (L.); $\text{BaA}'_2 + 3\text{H}_2\text{O}$, concentric needles (L.); $\text{CaA}'_2 + 3\frac{1}{2}\text{H}_2\text{O}$, needles (C. and S.), or $+ 2\text{H}_2\text{O}$, leaflets (C. and S.); $\text{CuA}'_2 + 2\frac{1}{2}\text{H}_2\text{O}$, bluish-green leaflets (C. and S.).

Chloride; large yellow prisms, m.p. 123° (L.; C. and S.; Karlsake and Morgan, J. Amer. Chem. Soc. 1908, 30, 828).

Amide; white lustrous prisms, m.p. 193° (L.; C. and S.); **anilide**, yellow needles, m.p. 154° (K. and M.); **o-toluidide**, white needles, m.p. 135° (K. and M.).

By the action of the sulphonyl chloride on benzene in the presence of aluminum chloride, 2:6-dinitro-1:3-dimethylphenyl phenyl sulphone, large lustrous plates, m.p. 178° , is obtained (K. and M.).

5:6-Dinitro-*m*-xylene 4-sulphonic acid; together with the 2:6-dinitro-derivative by treating a solution of *m*-xylene 4-sulphonic acid in acetic acid with a mixture of 3 parts of fuming nitric acid, 3 parts of fuming sulphuric acid, and 1 part of phosphorus pentoxide and heating the mixture on the water-bath until the evolution of red fumes ceases; by nitrating 5-nitro- and 6-nitro-*m*-xylene 4-sulphonic acids (Claus and Schmidt, Ber. 1886, 19, 1418). It crystallises in microscopic plates. KA' ; $\text{NaA}' + \text{H}_2\text{O}$, needles; $\text{BaA}'_2 + \frac{1}{2}\text{H}_2\text{O}$, colourless needles, or $+ 2\frac{1}{2}\text{H}_2\text{O}$, prisms; $\text{CuA}'_2 + 4\text{H}_2\text{O}$, bluish-green leaflets; $\text{PbA}'_2 + 4\frac{1}{2}\text{H}_2\text{O}$, tables.

Chloride; irregular crystals, m.p. 117° – 118° (C. and S.).

Amide; small colourless needles, m.p. 158° (C. and S.).

6-Bromo-2- (or 5-) nitro-*m*-xylene 4-sulphonic acid; from nitro-*m*-xylylidine 4-sulphonic acid by the Sandmeyer reaction (Sartig, Ann. 1885, 230, 333; Limpriht, Ber. 1885, 18, 2172). Colourless rhombic plates. $\text{KA}' + \text{H}_2\text{O}$, yellow prisms; $\text{BaA}'_2 + 3\frac{1}{2}\text{H}_2\text{O}$, yellow crystals, or fine needles.

p-Xylene; see *o*- and *m*-xylene; in coal tar; in Galician petroleum (Pawlewski, Ber. 1885, 18, 1915); by the action of methyl iodide and sodium on *p*-bromotoluene (Fittig and Glimmer, Ann. 1865, 136, 303; Bull. Soc. chim. 1865, (2) 4, 36; Jannasch, Ann. 1874, 171, 79; Bull. Soc. chim. 1871, (2) 15, 275; 1874, 22, 306); from *p*-dibromobenzene, methyl iodide and sodium (von Meyer, Ann. 1870, 166, 265; Bull. Soc. chim. 1870, 14, 405; Ber. 1870, 3, 753; Jannasch,

Ber. 1877, 10, 1354); from *p*-tolylmagnesium bromide and methyl sulphate in a yield of 75 p.c. (Werner and Zilkens, Ber. 1903, 36, 2116; Houben, *ibid.* 3083).

Monoclinic prisms, $a:b:c=2.32:1:2.34$, $\beta=69.5^\circ$ (Baeyer, Ann. 1888, 245, 141), m.p. 15° (Jannasch, Ann. 1874, 171, 80), or 13° (Reissert, Ber. 1890, 23, 2242); b.p. 138° ; D_4^{20} 0.8801 (Pinette, Ann. 1888, 243, 51); D_{25}^{20} 0.860 (Gladstone, Chem. Soc. Trans. 1891, 59, 290; cf. Neubeck, Zeitsch. physikal. Chem. 1887, 1, 601; von Hirsch, Ann. Phys. Chem. 1899 (ii), 69, 456); b.p. 137.5° ; D_{15}^{15} 0.8661; D_{25}^{15} 0.8593; $D_4^{14.4}$ 0.86619 (Perkin, Chem. Soc. Trans. 1896, 69, 1241; 1900, 77, 278); critical temperature 344.4° ; critical pressure, 35.0 (Altschul, Zeitsch. physikal. Chem. 1893, 11, 590); dielectric constant, density, refractive power (Landolt and Jahn, Zeitsch. physikal. Chem. 1892, 10, 300; Drude, *ibid.* 1897, 23, 309; Bruhl, J. pr. Chem. 1894, (2) 50, 140); capillarity constant (Schiff, Ann. 1884, 223, 67); magnetic behaviour (Schönrock, Zeitsch. physikal. Chem. 1893, 11, 785; Perkin); cryoscopic behaviour (Ampola and Rimatori, Gazz. chim. ital. 1897, 27, i, 38, 54) absorption spectrum in ultra violet (Mies, Zeitsch. wiss. Photochem. 1910, 8, 287); other physical constants (von Auwers, Ann. 1919, 419, 92).

For separation from its isomerides, see *o* and *m*-xylene. On oxidation with dilute nitric acid *p*-xylene yields *p* toluic acid, and with chromic acid terephthalic acid. For oxidation in presence of catalysts, &c., see *o*-xylene. When heated with concentrated hydriodic acid at 250° – 280° , *p*-xylene yields benzene, toluene, methylcyclohexane, and methylated penta methylene (Markownikow, Ber. 1897, 30, 1218). In separating *p*-xylene from coal-tar xylene by Jacobsen's method, Nölting and Palmer (Ber. 1891, 24, 1955) obtained ethylbenzene to the extent of two-thirds of the supposed *p* xylene content, and corresponding to an approximate proportion of 10 p.c. in the crude xylene, but Clarke and Taylor (J. Amer. Chem. Soc. 1923, 45, 830) did not find any evidence of the presence of ethylbenzene during the purification of commercial *p*-xylene.

p-Xylene on treatment with aluminium chloride at 100° in presence of hydrogen chloride yields mainly *m*-xylene (Heisse and Töhl, Ann. 1892, 270, 155). When *p*-xylene is heated with phenylcyanate in presence of aluminium chloride, the corresponding xylylanilide is obtained (Leuckart, J. pr. Chem. 1890, (2) 41, 301). By heating a mixture of benzhydro *p*-xylene, and phosphoric anhydride for 4 hours diphenyl-*p*-xylyl-methane, prismatic crystal m.p. 92° – 92.5° , is obtained. Like triphenyl methane, this yields dyes, similar to rosaniline by successive nitration, reduction, and oxidation (Hemilian, Ber. 1893, 16, 2360; Elbs, J. pr. Chem. 1887, (2) 35, 465). Unlike *o*- and *m*-xylene *p*-xylene does not react with diphenylcarbamic chloride in the presence of aluminium chloride (Lehmann and Bonhöffer, Ber. 1896, 19, 3231).

p-Xylene is converted into *p*-tolualdehyde, b.p. 204° – 205° , by means of Etard's reagent (Bornemann, Ber. 1894, 17, 1462). *p*-Xylene condenses with phthalic anhydride forming *p*-xylene-phthalic acid (Meyer, Ber. 1892, 15, 224). *p*-Xylylmercaptol condenses with methyl

ene iodide to form the *p*-mercaptal, m.p. 149° – 150° ; with ethylene bromide to form

m.p. 113° – 114° ; and with *p*-xylylene bromide to form $\text{C}_6\text{H}_4 \begin{array}{c} \text{CH}_2 \cdot \text{S} \cdot \text{CH}_2 \\ | \\ \text{CH}_2 \cdot \text{S} \cdot \text{CH}_2 \end{array} \text{C}_6\text{H}_4$, m.p. 192° – 193° (Kötz and Sevin, J. pr. Chem. 1901, (2) 64, 518). When *p*-xylene is heated with hydroxylamine hydrochloride in presence of aluminium chloride, a small amount of *p*-2-xylylidine is obtained (Graebe, Ber. 1901, 34, 1778). Ethyl chloroglyoxylate in presence of aluminium chloride converts *p*-xylene into ethyl *p*-xylyl-glyoxylate, colourless liquid, b.p. 155° – $156^\circ/10$ mm. The free acid, m.p. 75° , on heating with sulphuric acid at 100° , is converted into *p*-xylyl-carboxylic acid, and when heated with aniline it forms 2:5-dimethylbenzylideneaniline (Bouveau, Bull. Soc. chim. 1897, (3) 17, 363, 940). *p*-Xylene-2-oxyacetal, prepared similarly to the corresponding *o*- and *m*-compounds, boils at 278° – 279° , and has D_{15}^{15} 0.972; the aldehyde hydrate melts at 63° – 64° ; the oxime at 114° ; the semi-carbazone at 104° ; the derived *o*-*m*-dimethylcoumarone boils at 216° , and has D_{15}^{15} 1.041, and refractive index at 16° 1.549 (Stoermer and Schroeder, Ber. 1897, 30, 1700). Well-cooled *p*-xylene, subjected to the vapours of sulphuric anhydride at temperatures below 25° , yields di-*p*-xylylsulphone (in which the SO_2 group is in the meta-position), prismatic needles, m.p. 141° – 142° (Zorn and Brunel, Compt. rend. 1894, 119, 1224). This sulphone is obtained also together with chloro-*p*-xylene and *p*-xylene-sulphonyl chloride by the action of sulphuryl chloride on *p*-xylene in presence of aluminium chloride (Töhl and Eberhard, Ber. 1893, 26, 2940). When heated with sulphur, *p*-xylene forms 4:4'-dimethylstilbene and 4:4'-dimethyldibenzyl, the former being probably the primary product, and reduced to the latter by the hydrogen sulphide evolved (Aronstein and Nierop, Proc. K. Akad. Wetensch. Amsterdam, 1902, 5, 288; Rec. trav. chim. 1902, 21, 448). When oxidised electrochemically in dilute sulphuric acid at a lead dioxide anode, *p*-xylene yields *p*-tolualdehyde, *p*-xyloquinone, and *p*-xylylene dioxide (?), silky needles, m.p. 161° (Fichter and Stocker, Ber. 1914, 47, 2603; cf. Law and F. M. Perkin, Chem. Soc. Trans. 1907, 91, 258).

2:6-Dithiol-*p*-xylene, b.p. $145.5^\circ/11.5$ mm. (diacetyl-derivative, needles, m.p. 79.5° – 82.5° ; dipicryl-derivative, yellow crystalline solid, m.p. 251° – 255° ; dimethyl-derivative, needles, m.p. 92° – 94° ; *p*-xylene-2:6-diethylacetic acid, needles, m.p. 170.5° – 174.5°) is obtained from *p*-xylene through the disulphonyl derivative as in the case of *m*-xylene (Pollak and Schädler, Monatsh. 1918, 39, 129).

p-Xylene when heated to 700° by means of an electrically heated wire yields di-*p*-xylyl and products converted on oxidation into terephthalic and *p*-toluic acids, whilst at 800° *p*-dimethylstilbene is formed (H. Meyer and A. Hofmann, Monatsh. 1916, 37, 821). When treated with aqua regia *p*-xylene yields monochloro-, 2:5-dichloro-, and tetrachloro-*p*-xylene (Datta and Fernandes, J. Amer. Chem.

Soc. 1918, 38, 1809), and when brominated in presence of nitric acid a similar mixture of bromo-derivatives is obtained, together with *p*-toluic acid (Datta and Chatterjee, *ibid.* 2545).

p-Xylene reacts with phosphorus chloride in presence of aluminium chloride forming *p*-xylyl phosphorus chloride $C_6H_4(CH_2)_2PCl_2$, b.p. 253°–254°, m.p. –30°. The latter on treatment with chlorine yields the corresponding tetrachloride, m.p. 60°, which, on treatment with water or sulphur dioxide, is converted into *p*-xylyl phosphorus oxychloride,

b.p. 280°–281°. *p*-Xylene phosphinous acid, $C_6H_4(CH_2)_2PO_2H_2$, is formed when the corresponding chloride is treated with warm water. *p*-Xylene phosphonic acid, $C_6H_4(CH_2)_2PO(OH)_2$, colourless needles, m.p. 179°–180°, is obtained when either the tetrachloride or oxychloride is decomposed with water, and when heated it decomposes, forming metaphosphoric acid and *p*-xylene (Weller, Ber. 1888, 21, 1492; Michaelis and Panek, Ber. 1880, 13, 656). *p*-Xylene borochloride is a colourless fuming liquid, b.p. 205°; *p*-xylyl boric acid forms slender needles, m.p. 186°, and the oxide melts at 176° (Michaelis and Thévenot, Ann. 1901, 315, 19). For arsenic derivatives of *p*-xylene, see Michaelis and Pasel (J. pr. Chem. 1902, (2) 66, 130); Jacobs, Heidelberger and Rolf (J. Amer. Chem. Soc. 1918, 40, 1580); for hydrogenated derivatives of *p*-xylene, see Bayer (Ber. 1892, 25, 2122); Schiff (Ber. 1880, 13, 1407; Gazz. chim. ital. 1880, 10, 317); Renard (Ann. Chim. Phys. 1884, (6) 1, 223); Zelinsky and Naumow (Ber. 1898, 31, 3206).

p-Xylene when treated with acetyl chloride in presence of aluminium chloride yields *p*-xylyl methyl ketone, b.p. 224°–225°, $D_{20}^{25} 0.9962$ (Claus and Wollner), or b.p. 232°–233° (Errera). When heated in presence of 95 p.c. alcoholic ammonium hydrosulphide and sulphur, for 48 hours at 200°, the ketone yields *p*-xylyl-acetamide, m.p. 154°, which is converted on hydrolysis with 33 p.c. alcoholic potash into *p*-xylyl-acetic acid. The ketone when mixed with sodium, amyl nitrite and alcohol, forms the sodium salt of *p*-xylyl-2-formoxime,

together with isoxylylic acid (Claus and Wollner, Ber. 1895, 18, 1856; Errera, Gazz. chim. ital. 1891, 21, 94; Guerbet, Compt. rend. 1897, 125, 34; Söderbaum, Ber. 1894, 27, 658). *p*-Xylyl ethyl ketone, obtained similarly to the methyl-compound, is a highly refractive liquid, b.p. 237°–238° (Claus and Fickert, Ber. 1886, 19, 3182; Claus, J. pr. Chem. 1891, (2) 43, 138); for further information regarding ketones derived from *p*-xylene, see Elbs and Olberg (Ber. 1886, 19, 408); Elbs (J. pr. Chem. 1887, (2) 35, 465); Hemilian (Ber. 1883, 16, 2360); Claus and Murtfeldt (Ber. 1887, 20, 1377); Schopff (Ber. 1891, 24, 3766); Wege (*ibid.* 3540); Strzelecki (Bull. Acad. Sci. Cracow, 1902, 12); Straßmann (Ber. 1889, 22, 1229); Collet (Bull. Soc. chim. 1897, (3) 17, 506; Compt. rend. 1897, 125, 305); Klages and Allendorf (Ber. 1898, 31, 1298); Kunckell (Ber. 1897, 30, 577); Limpricht (Ann. 1895, 286, 306); Claus (J. pr. Chem. 1892, (2) 46, 474); Layraud (Bull. Soc. chim. 1906, (3) 35, 223).

Antimony trichloride may be substituted for aluminium chloride in condensing acid chlorides of moderately high boiling-point with hydrocarbons (Comstock, Amer. Chem. J. 1896, 18, 547).

o-Chloro-*p*-xylene; by chlorinating boiling *p*-xylene (Lauth and Grimaux, Zeit. für Chem. 1867, 3, 381); by chlorinating *p*-xylene in sunlight (Radziewanowski and Schramm, Akad. Wiss. Krakau, 1898, 61); from the corresponding alcohol by distillation with hydrochloric acid (Curtius and Sprenger, J. pr. Chem. 1900, (2) 62, 111); by the action of *s*-dichloromethylether on toluene in the presence of anhydrous zinc chloride, di-*p*-tolylmethane being formed also (Stephen, Short and Gladding, Chem. Soc. Trans. 1920, 117, 510). Oil, b.p. 192° (L. and G.), 200°–202° (R. and S.), 90°/20 mm. (C. and S.), 92°–94°/20 mm., or 192°/760 mm. (S., S. and G.).

o-Dichloro-*p*-xylene, *p*-xylylene chloride $C_6H_4(CH_2Cl)_2$; by chlorinating boiling *p*-xylene (L. and G.); by chlorinating *p*-xylene in sunlight (R. and S.); by distilling the glycol, $C_6H_4(CH_2OH)_2$, with hydrochloric acid (Grimaux, Zeit. für Chem. 1870, 6, 394); from *p*-xylene and phosphorus pentachloride at 190° (Colson and Gautier, Ann. Chim. Phys. 1887, (6) 11, 22; Bull. Soc. chim. 1886, (2) 45, 6; Colson, Compt. rend. 1884, 99, 40; Bull. Soc. chim. 1886, (2) 46, 2); together with benzyl chloride by warming a mixture of benzene, *s*-dichloromethylether and anhydrous zinc chloride for 10 hours (S., S. and G.); from benzyl chloride similarly, by heating for 18 hours at 30°–35° (S., S. and G.). Leaflets or rhombic tables, m.p. 100° (L. and G.), or 100.5° (S., S. and G.); b.p. when slightly impure, 120°/20 mm. (S., S. and G.), or b.p. 240°–258° with decomposition; $D_{20}^{25} 1.417$ (C.). On oxidation it yields terephthalaldehyde, m.p. 116°–117°, and terephthalic acid, m.p. 140° (S., S. and G.; Hönlitz, Monatsh. 1889, 9, 1153), and when heated with water at 170°–180° the corresponding glycol is formed.

2-*o*-(4-)Dichloro-*p*-xylene,

by keeping a mixture of *o*-chlorotoluene, *s*-dichloromethylether and zinc chloride monohydrate for 24 hours (S., S. and G.). Colourless oil, b.p. 124°/20 mm.

*Symm.-tetra-*o*-chloro-*p*-xylene*, $C_6H_4(CHCl)_2$; by heating *p*-xylene with phosphorus pentachloride at 190° (Colson and Gautier, Bull. Soc. chim. 1886, (2) 45, 9; Ann. Chim. Phys. 1887, (6) 11, 24; Colson, Bull. Soc. chim. 1886, (2) 46, 2). Crystals, m.p. 93°, $D_{20}^{25} 1.006$. On hydrolysis with water it yields terephthalaldehyde (Colson and Gautier, Compt. rend. 1886, 102, 689).

o-Pentachloro-*p*-xylene; together with the *o*-hexachloro-derivative by heating *p*-xylene with excess of phosphorus pentachloride in a sealed tube at 100° (Colson and Gautier).

o-Hexachloro-*p*-xylene; from *p*-xylene in a similar manner to the pentachloro-compound (Colson and Gautier, Ann. Chim. Phys. 1887, (6) 11, 27; Compt. rend. 1886, 102, 689; Bull. Soc. chim. 1886, (2) 45, 507). Transparent matted crystals, m.p. 111°. When heated with water or sodium hydroxide solution it yields terephthalic acid.

2-Chloro-*p*-xylene; by chlorinating *p*-xylene in presence of iodine (Kluge, Ber. 1885, 18, 2099); together with the 2:5 dichloro- and the tetrachloro-derivative by treating *p*-xylene with *aqua regia* (Datta and Fernandes, J. Amer. Chem. Soc. 1916, 38, 1809). Oil, b.p. 186°/767 mm., solidifying to crystals, m.p. 2° (K.).

2:5-Dichloro-*p*-xylene; by treating *p*-xylene with *aqua regia* (D. and F.); by chlorinating *p*-xylene or its monochloro-derivative (K.); from 2-chloro-*p*-5-xylidine (K.). Plates or flat needles, m.p. 71°, b.p. 221°.

Tetrachloro-*p*-xylene; by chlorinating *p*-xylene in chloroform solution in presence of iron (Rupp, Ber. 1896, 29, 1628); by treating *p*-xylene with *aqua regia* (D. and F.). Colourless silky needles, m.p. 218°. When heated with nitric acid and potassium permanganate for 8 hours in a sealed tube at 180° tetrachloro-*p*-toluic acid, needles, m.p. 212°, is formed.

***ω*-Bromo-*p*-xylene**, *p*-xylyl bromide,

by treating toluene with *s*-dibromomethylether in presence of zinc chloride monohydrate (Stephen, Short and Gladding, Chem. Soc. Trans. 1920, 117, 510); by brominating heated *p*-xylene (Radziszewski and Wispek, Ber. 1882, 15, 1743; 1885, 18, 1279; Atkinson and Thorpe, Chem. Soc. Trans. 1907, 91, 1687); by brominating *p*-xylene in presence of sunlight (Schramm, Ber. 1885, 18, 1277). Colourless needles, m.p. 35.5°, b.p. 218°–220°/740 mm (R. and W.), or m.p. 38°, b.p. 109°/15 mm. (S., S. and G.). When treated with alcoholic potassium thiocyanate it yields *p*-xylyl thiocyanate, m.p. 21.5°–22.5° (Strzelecka, Bull. Acad. Sci. Cracow, 1909, 731; cf. Kosmos, 1910, 35, Radziszewski-Festband, 585), and with alcoholic potassium sulphide it yields *p*-xylyl sulphide, m.p. 76°, which, on oxidation, yields the corresponding sulfoxide, m.p. 117°, whilst both the sulphide and the sulfoxide are oxidised by potassium permanganate to *p*-xylyl-sulphone, m.p. 197° (Martynowicz, Kosmos, 1910, 35, Radziszewski-Festband, 594). *p*-Xylyl bromide, when treated with potassium cyanide, yields *p*-xylyl cyanide, m.p. 18°, b.p. 242°–243°, $D_{20}^{25} 0.9922$, which is converted by treatment with hydrogen peroxide and potassium hydroxide into the acetamide, m.p. 184° (R. and W.).

***ω*-Dibromo-*p*-xylene**, *p*-xylylene bromide,

together with benzyl bromide by treating benzene with *s*-dibromomethylether in presence of anhydrous zinc chloride with cooling (Stephen, Short and Gladding); or by the action of bromine on heated *p*-xylene (Grimaux, Zeit. für Chem. 1870, 6, 394; Radziszewski and Wispek; Kipping, Chem. Soc. Trans. 1888, 53, 21; Atkinson and Thorpe; Colson, Bull. Soc. chim. 1886, (2) 46, 2; Compt. rend. 1884, 99, 40; 1887, 104, 428; Ann. Chim. Phys. 1885, (6) 6, 119); by the action of bromine on cold *p*-xylene in presence of sunlight (Schramm, Ber. 1885, 18, 1277; Allain-Le Canu, Compt. rend. 1893, 118, 534). Needles, rhomboidal plates, or large prisms, m.p. 143.5°, b.p. 340°–350° (R. and W.), $D_{20}^{25} 2.012$ (C.; A. and T.; A.-Le C.), or m.p. 144° (S., S. and G.).

When reduced with zinc dust in glacial

acetic acid solution, a mixture of *p*-xylene and a polymeride of *p*-xylylene

is obtained, but on reduction with stannous chloride in acetic acid solution, *p*-xylyl acetate, b.p. 227°, is formed (Thiele and Balhorn, Ber. 1904, 37, 1463). When boiled with alcoholic potassium hydrosulphide saturated with hydrogen sulphide, *p*-xylylene bromide yields *p*-xylylene hydrosulphide and the monoethyl-ether of *p*-xylylene glycol, b.p. 250°–252°. The former in the presence of hydrogen chloride condenses with aliphatic aldehydes or ketones forming amorphous indefinite products, but with aromatic aldehydes well-crystalline duplo-compounds are formed which are very stable, e.g. duplo-*p*-xylylenebenzylidenemercaptal,

m.p. 248°–249°, is prepared by passing hydrogen chloride into an ice-cold mixture of equal molecular proportions of benzaldehyde and *p*-xylylene hydrosulphide. When oxidised with acid permanganate, the duplo-compound yields the corresponding tetrasulphone (Autenrieth and Beuttel, Ber. 1909, 42, 4346; Kötze and Sevin, Ber. 1900, 33, 729). *p*-Xylylene dibromide, when treated in acetone solution with sodium iodide, yields *p*-xylylene iodide (Finkelstein, Ber. 1910, 43, 1528; Knoll and Co., D. R. P. 230172 of 1908). The di-iodide melts at 175° (F.) or 170° (Grimaux, Zeit. für Chem. 1870, 6, 395). *p*-Xylylene bromide differs in some respects from *o*-xylylene bromide in its action on amines. It does not form ring compounds of the type of dihydroisindole with primary amines, nor does it form ammonium bromides with secondary amines (Manoukian, Ber. 1901, 34, 2082). When treated with fuming nitric acid, *p*-xylylene bromide is converted into terephthalaldehyde, terephthalaldehydic acid, and a compound, $\text{C}_{14}\text{H}_{10}\text{Br}_2\text{O}_4$, needles, m.p. 80° (Löw, Ber. 1885, 18, 2072).

***ω*- ω -Tribromo-*p*-xylene**; by brominating heated *p*-xylene (Atkinson and Thorpe), or cold *p*-xylene in sunlight (Allain-Le Canu, Bull. Soc. chim. 1894, (3) 11, 382; Compt. rend. 1893, 118, 534). Orthorhombic plates, m.p. 116° (A.-Le C.), or m.p. 106° (A. and T.; Löw, Ann. 1885, 231, 363). When hydrolysed with sodium hydroxide the aldehyde-alcohol, $\text{CHO} \cdot \text{C}_6\text{H}_4 \cdot \text{CH}_2\text{OH}$, colourless oily liquid, is formed (A.-Le C.).

Symm.- ω -tetrabromo-*p*-xylene, $\text{C}_6\text{H}_4(\text{CHBr})_2$; by passing dry bromine into *p*-xylene heated first at 140°, then at 170°, and finally at 200° (Hönig, Monatsh. 1889, 9, 1150). Glistening monoclinic prisms, m.p. 169°.

***ω*-Hexabromo-*p*-xylene**; in small yield by the direct bromination of *p*-xylene, but better by brominating ω -tetrabromo-*p*-xylene at 170°–180° (Thiele and Balhorn, Ber. 1904, 37, 1463). Needles, m.p. 194°. When heated with nitric acid at 130°–140° terephthalic acid is formed.

2-Bromo-*p*-xylene; by the action of bromine on cold *p*-xylene in the dark (Fittig and Jannasch, Ann. 1869, 151, 283; Jannasch, Ann. 1874, 171, 79; Ber. 1884, 17, 2709; Jacobsen, Ber. 1884, 17, 2379; 1885, 18, 356; Schramm, Ber. 1885, 18, 1276). Tables or leaflets, m.p. 10° (Jannasch), b.p. 199.5°–200.5°; or

m.p. 9-9°, b.p. 205-5°/755 mm. (Jacobsen). On oxidation with chromic acid in acetic acid solution, it yields bromo-*p*-toluic acid. The magnesium derivative condenses with chloral, forming $\beta\beta$ -trichloro- α -xylylethyl alcohol, b.p. 158°/10 mm., which on prolonged boiling with aqueous potassium carbonate is converted into xylylaldehyde (Savariau, Compt. rend. 1908, 146, 297; Carré, *ibid.* 1909, 148, 1108). For the behaviour with the lead salt of aromatic thiophenols, see Bourgeois (Ber. 1895, 28, 2312).

2:5-Dibromo-*p*-xylene; together with 2:6-dibromo-*p*-xylene by brominating *p*-xylene (Blanksma, Chem. Weekblad. 1913, 10, 136); from 5-bromo-*p*-2-xylydine by the Sandmeyer reaction (B.); by brominating *p*-xylene in the presence of iodine (Fittig, Ahrens and Mattheides, Ann. 1867, 147, 26). Leaflets, or monoclinic tables (Miers, Chem. Soc. Trans. 1890, 57, 975), m.p. 75° (Jannasch, Ber. 1877, 10, 1357), b.p. 261° (Jacobsen, Ber. 1885, 18, 358), b.p. 141°/15 mm. or 149-5°/21 mm. (Auwers and Baum, Ber. 1896, 29, 2329). When heated with concentrated sulphuric acid at 215° it yields a small quantity of a liquid isomeride, b.p. 260°-265°, probably impure 2:6-dibromo-*p*-xylene (Koch, Ber. 1890, 23, 2318). When oxidised with chromic acid in acetic acid solution the dibromo-*p*-toluic acid, m.p. 195°, is formed (Schultz, Ber. 1885, 18, 1762).

2:6-Dibromo-*p*-xylene; in small quantity and in an impure condition by brominating *p*-xylene (Jacobsen; Blanksma); from 3:5-dibromo-*p*-2-xylydine (Blanksma). Colourless pearly plates, m.p. 32° (B.).

Tetrabromo-*p*-xylene; together with mono- and dibromo-*p*-toluene and *p*-toluic acid by brominating *p*-xylene in presence of nitric acid (Datta and Chatterjee, J. Amer. Chem. Soc. 1916, 38, 2545); by brominating *p*-xylene (Jacobsen), 1:4-dimethyl-2-ethylbenzene (Bodroux, Bull. Soc. chim. 1898, (3) 19, 888), or hexahydro-*p*-xylene (Zelinsky and Naumow, Ber. 1898, 31, 3208) in presence of aluminium bromide. Long fine needles, m.p. 253°, b.p. about 355° (J.). When heated with potassium permanganate and nitric acid in a sealed tube for 8 hours at 180° it yields tetrabromoterephthalic acid (Rupp, Ber. 1896, 29, 1625).

For iodo-derivatives of *p*-xylene, see Klages and Liocke (J. pr. Chem. 1900, (2) 61, 325); Edinger and Goldberg (Ber. 1900, 33, 2875); Grimaux (Zeit. für Chem. 1870, 6, 395); Ullmann (Ann. 1904, 332, 38); Willgerodt and Plocksties (J. pr. Chem. 1912, (2) 85, 198).

Chlorobromo-*p*-xylene; by brominating chloro-*p*-xylene in presence of iron (Willgerodt and Wolfen, J. pr. Chem. 1889, (2) 39, 403). Pearly laminae, m.p. 66°.

Dichlorobromo-*p*-xylene; needles, m.p. 96° (W. and W.).

Trichlorobromo-*p*-xylene; needles which sublime, m.p. 219° (W. and W.).

Chlorodibromo-*p*-xylene; by brominating chlorobromo-*p*-xylene in presence of iron. Needles, m.p. 93° (W. and W.).

Dichlorodibromo-*p*-xylene; in small yield by brominating dichloro-*p*-xylene. Needles which sublime, m.p. 226° (W. and W.).

Chlorotribromo-*p*-xylene; by brominating *p*-xylene in presence of iron. Sublimes in needles, m.p. 224° (W. and W.).

***o*-Nitro-*p*-xylene**; similarly to *o*-nitro-*m*-xylene (L.); m.p. 11°-12°; b.p. 150°-151°/85 mm. (slight decomp.); D_4^{20} 1.1234, n_D^{20} 1.58106 at 20° (Konowaloff, J. Russ. Phys. Chem. Soc. 1899, 31, 254).

2-Nitro-*p*-xylene; by the action of fuming nitric acid on ice-cold *p*-xylene (Jannasch, Ann. 1875, 176, 55; Schaumann, Ber. 1878, 11, 1537). Pale yellow liquid, b.p. 238-5°-239°/789 mm.; D_4^{20} 1.132 (Nölting and Forel, Ber. 1885, 18, 2668). When oxidised with potassium ferrieyanide it yields nitro-*p*-toluic acid, nitroterephthalic acid, and a substance,

(Noyes, Amer. Chem. J. 1888, 10, 472). On reduction with zinc dust and water it yields the hydroxylamine (Lumière, Lumière and Seyewitz, Bull. Soc. chim. 1894, (3) 11, 1038; Bamberger and Rising, Ann. 1901, 316, 257; cf. Bamberger, Ann. 1921, 424, 233, 297; Bamberger and Tschirner, Ber. 1900, 33, 955); and on electrolytic reduction in sulphuric acid solution 2-amino-*p*-5-xenol, pale yellow needles, m.p. 238° (decomp.), is formed (Gattermann, Ber. 1894, 27, 1927). 2-Nitro-*p*-xylene cannot be readily sulphated with sulphuric acid (Carslake and Huston, J. Amer. Chem. Soc. 1914, 36, 1244).

β -2:3-Dinitro-*p*-xylene; together with 2:6- and 2:5-dinitro-*p*-xylenes, by nitrating *p*-xylene (Rammer, Bull. Soc. chim. 1868, (2) 9, 434; Fittig, Ann. 1865, 136, 307; 1868, 147, 17; Jannasch, Ann. 1874, 171, 79; Ber. 1881, 14, 1146; 1882, 15, 2304; Nölting, Ber. 1886, 19, 144; Kostanecki, Ber. 1886, 19, 2318; Lellmann, Ann. 1885, 228, 252; Blanksma Chem. Weekblad, 1910, 7, 727). Lustrous, monoclinic prisms, m.p. 93°, $a:b:c = 0.8695:1:0.63818$, $\beta = 81^\circ 14' 52''$ (Barner, Ber. 1882, 15, 2302).

(γ)-2:5-Dinitro-*p*-xylene; in small quantity by nitrating *p*-xylene (L.). Long yellow vitreous needles, m.p. 147°-148°.

2:6-Dinitro-*p*-xylene; by nitrating *p*-xylene; from 3:5-dinitro-*p*-2-xylydine. Long slender needles, m.p. 123-5°-124° (Nölting and Geissmann, Ber. 1886, 19, 144).

***o*-Nitronitroso-*p*-xylene**; by reducing a mixture of *o*- and *m*-dinitro-*p*-xylenes (obtained by direct nitration of *p*-xylene) with hydroxylamine hydrochloride in methyl alcoholic potassium hydroxide solution, extracting unchanged *m*-dinitro-compound with ether, and adding hydrochloric acid to the cooled solution (Meisenheimer and Patzig, Ber. 1906, 39, 2526). Slightly yellow crystals, m.p. 130-5°.

2:3:6-Trinitro-*p*-xylene; by warming *p*-xylene with a mixture of nitric and sulphuric acids (Fittig and Glinzer, Ann. 1865, 136, 307; Nölting and Geissmann, Ber. 1886, 19, 144). Large monoclinic needles, m.p. 137° (F. and G.) or 139°-140° (N. and G.).

Trinitro-*p*-xylene, m.p. 127°, was obtained by Schiff (Ber. 1880, 13, 1407; Gazz. chim. Ital. 1880, 10, 317) by treating hexahydro-*p*-xylene with nitric acid. With hydrazine hydrate it yields 3:5-dinitro-*p*-2-xylylhydrazine, yellow prisms, m.p. 180° (Gina, Gazz. chim. Ital. 1916, 40, ii. 166), and, on reduction with alkali sulphides, is converted into nitro-*p*-xylydine and phonic acid (Fittig, Ahrens and Mattheides,

Ann. 1867, 147, 24; Blankensma, Rec. trav. chim. 1905, 24, 46).

ω-(4)-Chloro-2-nitro-*p*-xylene; together with 3:3'-dinitro-di-*p*-tolylmethane by adding a little more than the theoretical quantity of aluminium chloride to a mixture of *o*-nitro-toluene and *s*-chloromethyl-ether (Stephen, Short and Gladding, Chem. Soc. Trans. 1920, 117, 510). It melts at 45° and has a violent action on the skin, and the vapour attacks the eyes and nose.

Nitro-ω-dichloro-*p*-xylene; by dissolving *p*-xylylene chloride in fuming nitric acid (Grimaux, Zeit. für Chem. 1871, 7, 598). Small plates, m.p. 45°.

2:5-Dichloro-dinitro-*p*-xylene; by nitrating 2:5-dichloro-*p*-xylene with nitric and sulphuric acids (Kluge, Ber. 1885, 18, 2098). Small needles, m.p. 225°.

2-Bromo-5-nitro-*p*-xylene; from 5-nitro-*p*-2-xylydine (Blankensma, Chem. Weekblad, 1913, 10, 136). Colourless crystals, m.p. 70°.

2-Bromo-6-nitro-*p*-xylene; from 6-nitro-*p*-2-xylydine (Blankensma). Pale yellow crystals, m.p. 38°.

2-Bromo-3:5-dinitro-*p*-xylene; by the action of sunlight, or more rapidly by the action of heat, on 3:5-dinitro-*p*-xylene-2-diazoperbromide (Fries and Noll, Ann. 1912, 389, 305). It melts at 117°.

2:5-Dibromo-3-nitro-*p*-xylene; by heating 2:5-dibromo-*p*-xylene with nitric acid and acetic acid on the water-bath until dissolved (Auwers and Baum, Ber. 1896, 29, 2329). It melts at 111°-112° (Fittig, Ann. 1868, 147, 28) or 106°, and boils at 199°/20 mm. (A. and B.).

2:3-Dibromo-5-nitro-*p*-xylene; from 3-bromo-5-nitro-*p*-2-xylydine by the Sandmeyer reaction (Blankensma). Colourless crystals, m.p. 99°.

3:5-Dibromo-2-nitro-*p*-xylene; from 3:5-dibromo-6-nitro-*p*-2-xylydine by the elimination of the amino-group (Blankensma). Colourless crystals, m.p. 83°.

2:6-Dibromo-3:5-dinitro-*p*-xylene; by nitrating 2:6-dibromo-*p*-xylene or 3:5-dibromo-2-nitro-*p*-xylene with nitric and sulphuric acids (Blankensma). Colourless crystals, m.p. 190°.

2:5-Dibromo-3:6-dinitro-*p*-xylene; in small quantity together with 2:5-dibromo-3-nitro-*p*-xylene by nitrating 2:5-dibromo-*p*-xylene (Auwers and Baum). Colourless needles, m.p. 225°.

5-Nitro-2:3-dinitroso-*p*-xylene; by heating 3:5-dinitro-*p*-xylyl-2-azoimide at 105°-130° (Fries and Noll, Ann. 1912, 389, 305). It melts at 81°. It is probable that this compound actually has the constitution of an isooxadiazole oxide and is not a true dinitroso-derivative.

Chlorobromonitro-*p*-xylene; from chlorobromo-*p*-xylene and fuming nitric acid (Willgerodt and Wolfen, J. pr. Chem. 1889, (2) 39, 408). Yellowish needles, m.p. 99.5°.

6-Chloro-3-bromo-2:5-dinitro-*p*-xylene; by heating chlorobromonitro-*p*-xylene with fuming nitric acid (W. and W.). Small crystals, m.p. 245°.

p-Xylene 2-sulphonic acid; from the sulphonyl chloride (Jacobsen, Ber. 1878, 11, 17); by the action of copper powder on a sulphuric acid solution of *p*-xylene-2-diazonium sulphate saturated with sulphur dioxide (Gattermann,

Ber. 1899, 32, 1141); by treating *p*-xylene in carbon disulphide solution with sulphur dioxide in presence of aluminium chloride and hydrogen chloride at 0° (Knoevenagel and Kenner, Ber. 1908, 41, 3315). Flat needles, m.p. 84°-85° (K. and K.; Moschner, Ber. 1901, 34, 1257). When treated in the cold with acetic anhydride, acetic acid and a drop of concentrated sulphuric acid, it yields *p*-xylene 2-sulphinic anhydride, $O[SO \cdot C_6H_4(CH_3)_2]_2$, m.p. 68°-69°. The latter compound decomposes *in vacuo*, forming *p*-xylene 2-sulphonic acid and *p*-xylene disulphoxide, white tables, m.p. 70°-72°; the same products are formed when *p*-xylene sulphonic acid is heated in a sealed tube at 120°-130° (Knoevenagel and Polack, Ber. 1908, 41, 3323). On reduction with zinc dust and sulphuric acid, *p*-xylene 2-sulphinic acid yields the corresponding mercaptan, b.p. 205°-206° (Gattermann, Ber. 1899, 32, 1136).

p-Xylene 2-sulphonic acid; by sulphonating crude xylene (Crafts, Compt. rend. 1891, 114, 1110); by dissolving *p*-xylene in faintly fuming sulphuric acid (Beilstein and Wahlforss, Ann. 1865, 133, 38; Fittig and Glinzer, Ann. 1866, 136, 505; Jacobsen, Ber. 1877, 10, 1009; 1878, 11, 22; Remsen and Emerson, Amer. Chem. J. 1886, 8, 265); by reducing sodium dibromo-*p*-xylene sulphonate with sodium amalgam (Moody and Nicholson, Chem. Soc. Trans. 1890, 58, 974). Large tables or long flat prisms $+2H_2O$ (J.), m.p. 48°, b.p. 149°/0 mm. (Krafft and Wilke, Ber. 1900, 33, 3207). $NaA' + H_2O$ (J.), orthorhombic tables, $a:b:c=1.0767:1:1.4882$ (Miers, Chem. Soc. Trans. 1890, 58, 978); KA' (F. and G.); $KA' + H_2O$; BaA'_2 , irregular crystals; $CuA'_2 + 8H_2O$, pale blue tridinic prisms; $ZnA'_2 + 10H_2O$.

Chloride; large flat prisms, m.p. 24°-26° (J.), b.p. 77°/0 mm. (K. and W.).

Amide; long needles, m.p. 147°-148° (J.; Moschner, Ber. 1901, 34, 1257).

p-Xylene when treated with sulphuryl chloride in presence of aluminium chloride forms *p*-xylene 2-sulphonyl chloride, chloro-*p*-xylene and di-*p*-xylylsulphone (Töhl and Eberhard, Ber. 1893, 26, 2940). *p*-Xylene sulphonic acid is converted into terephthalic acid by fusion with lead peroxide and potassium hydroxide (Graebe and Krafft, Ber. 1906, 39, 2507).

p-Xylene 2:6(?)-disulphonic acid; by warming the monosulphonyl chloride with fuming sulphuric acid (Holmes, Amer. Chem. J. 1891, 13, 372; Pfannenstilk, J. pr. Chem. 1892, (2) 46, 152). Needles. $BaA'' + 3H_2O$; $CaA'' + 4H_2O$; $MgA'' + 7H_2O$; $PbA'' + 3H_2O$; $Ag_2A'' + H_2O$; all of these salts are very hygroscopic (H.).

Chloride; white radiating tufts, m.p. 72°-74° (H.), or 74°-75° (P.).

Amide; microscopic plates, m.p. 294°-295° (decomp.) (H.), or 250° (P.).

Chloro-*p*-xylene sulphonic acid; from chloro-*p*-xylene and fuming sulphuric acid (Kluge, Ber. 1888, 18, 2099). Crystals. $NaA' + H_2O$, prisms; $BaA'_2 + H_2O$, needles.

2-Bromo-*p*-xylene 5-sulphonic acid; from *p*-2-xylydine 5-sulphonic acid by the Sandmeyer reaction (Nölting and Kohn, Bull. Soc. Ind. Mulhouse, 1888, 58, 636; Ber. 1890, 19, 137). It is probably identical with the compound obtained by Jacobsen (Ber. 1896, 17, 2979) by sulphonating bromo-*p*-xylene. $BaA'_2 + 2H_2O$

(N. and K.); BaA' , thin six-sided plates or small prisms; $\text{NaA}' + \text{H}_2\text{O}$, long thin prisms or rhombic six-sided plates (J.).

Chloride; small prisms, m.p. $77^\circ\text{--}78^\circ$ (N. and K.).

Amide; small white scales, m.p. $200^\circ\text{--}201^\circ$ (N. and K.), or flat prisms, m.p. 206° (J.).

3:6-Dibromo-*p*-xylene 2-sulphonic acid; by sulphonating 3:6-dibromo-*p*-xylene with fuming sulphuric acid (20 p.c. SO_3) at 80° (Moody and Nicholson, Chem. Soc. Trans. 1890 57, 974). Glistening silky needles, m.p. 151° (decomp.). $\text{NaA}' + \text{H}_2\text{O}$, microscopic needles BaA' , scales or flat needles.

Chloride; flat needles, m.p. $78^\circ\text{--}79^\circ$.

Amide; thin pearly plates or thin rhombic plates, m.p. 198° .

3-Nitro-*p*-xylene 2-sulphonic acid; together with the 6-nitro-derivative and small quantities of the 5-nitro-derivative by nitrating *p*-xylene 2-sulphonic acid; the products are separated preferably by fractional crystallisation of the sulphonyl chlorides (Carslake and Huston, J. Amer. Chem. Soc. 1914, 36, 1244; 1915, 37 2119). Long deliquescent plates, m.p. $143^\circ\text{--}145^\circ$.

Chloride; m.p. $109.5^\circ\text{--}110.5^\circ$, is also formed together with 6-nitro-*p*-xylene 2-sulphonyl chloride by nitrating *p*-xylene 2-sulphonyl chloride.

Amide; m.p. $191^\circ\text{--}192^\circ$; *anilide*, m. $181.5^\circ\text{--}182.5^\circ$.

Phenyl-ester; m.p. $83^\circ\text{--}83.5^\circ$ (C. and H.).

5-Nitro-*p*-xylene 2-sulphonic acid; see above very hygroscopic needle-like plates $+ \text{H}_2\text{O}$ which lose H_2O at 108° and then melt at $138^\circ\text{--}140^\circ$.

Chloride; m.p. $74.5^\circ\text{--}75.5^\circ$, is also obtained together with 6-nitro-*p*-xylene 2-sulphonyl chloride by the action of chlorosulphonic acid on 2-nitro-*p*-xylene.

Amide; m.p. $197^\circ\text{--}198^\circ$; *anilide*, m.p. $130.5^\circ\text{--}131^\circ$.

Phenyl-ester; m.p. $120^\circ\text{--}120.5^\circ$ (C. and H.).

6-Nitro-*p*-xylene 2-sulphonic acid; see above plates $+ \text{H}_2\text{O}$, which darken at 128° and do not melt at 200° .

Chloride; m.p. $60^\circ\text{--}61^\circ$.

Amide; m.p. $172^\circ\text{--}173^\circ$; *anilide*, m. $133^\circ\text{--}144^\circ$.

Phenyl-ester; m.p. $117^\circ\text{--}118^\circ$.

Xylidines. (Aminoxylenes, or Aminodimethylbenzenes.) Theory predicts the existence of six isomeric aminodimethylbenzenes, and all are known. They are obtained by the reduction of the corresponding nitro-compounds with iron and hydrochloric acid, or with iron powder and acetic acid, or, in the case of the commercial products, with iron turnings and hydrochloric acid. Commercial xylidine contains *o*-3-xylidine, *o*-4-xylidine, *m*-2-xylidine, *m*-4-xylidine, and *p*-2-xylidine. The chief constituents are *m*-4-xylidine and *p*-2-xylidine. The percentage of the former may be estimated by converting the bases into the hydrochlorides or acetates, as these salts of *m*-4-xylidine are insoluble in water. When glacial acetic acid is used as precipitant, equal quantities of the acid and base give the best results. More accurate results are obtained, however, by converting the acetate into the bromide. *m*-4-Xylidine takes up 1 atom of bromine, and although *m*-2-xylidine behaves in a similar manner, its salts, particularly the hydrochloride, are readily soluble in water. The other bases form dibromides with bromine (Vaubel, Zeitsch. anal. Chem. 1897, 36, 285).

larly the hydrochloride, are readily soluble in water. The other bases form dibromides with bromine (Vaubel, Zeitsch. anal. Chem. 1897, 36, 285).

p-Xylidine may be obtained from commercial xylidine by gradually adding the latter to fuming sulphuric acid (15–20 p.c. SO_3) in such proportions that exactly 1 mol. xylidine is used with each mol. of sulphuric anhydride. The mixture is heated for some time on the water-bath, cooled, and then treated with water, when the sparingly soluble *m*-xylidine sulphonic acid is precipitated. The free acids contained in the mother-liquor are converted into their sodium salts; the sodium salt of *p*-xylidine sulphonic acid separates first, that of the *m*-xylidine sulphonic acid being very soluble (Witt, Nölting and Forel, Bull. Soc. Ind. Mulhouse, 1888, 53, 630; Ber. 1885, 18, 2664; Witt, Dingl. poly. J. 260, 95). *p*-Xylidine may also be separated from its isomerides by means of the benzylidene derivative, which is converted into the free base subsequently by hydrolysis (Limpach, Eng. Pat. 11822 of 1886; Fr. Pat. 178616; D. R. P. 39947 of 1886; Bayer & Co., D. R. P. 71969 of 1893). *m*-2-Xylidine may be obtained from commercial xylidine by converting the bases into the sulphates, allowing the solution of the salts to crystallise, and fractionating the mixture of bases obtained from the mother-liquor from the last crop of crystals. The portion distilling at $212^\circ\text{--}216^\circ$ is acetylated, and the mixture of acetyl-derivatives is boiled for a few hours with 4 times its weight of 25 p.c. sulphuric acid. On cooling, the greater part of the aceto-*m*-2-xylidide separates unchanged, the remainder being extracted from the previously diluted mother-liquor by means of ether. The acetyl-derivative is then hydrolysed by heating at 150° with concentrated hydrochloric acid, or at 200° with 3 times its weight of 70–75 p.c. sulphuric acid. *m*-2-Xylidine may be obtained also from commercial xylidine by heating the mixture of bases, obtained from the mother-liquor from the sulphates (see above), for 24 hours with an equal weight of glacial acetic acid, and distilling the product. The portion distilling below 300° is then treated with acetic anhydride, and the acetyl-derivatives boiled with 25 p.c. sulphuric acid and isolated as above (Nölting and Pick, Ber. 1888, 21, 3150). The *p*- and *m*-xylidines may also be separated by means of benzaldehyde, with which the *p*-isomeride yields di-*p*-amino-di-*p*-xylyl-phenyl-methane, m.p. 208° (Schultz, J. pr. Chem. 1907, (2) 76, 331). For use in the preparation of colouring matters, Limpach (Eng. Pat. 6890 of 1888; J. Soc. Chem. Ind. 1889, 8, 281) described the following method for separating the xylidines from the commercial product; 121 grms. of commercial xylidine are treated with 30 grms. of 100 p.c. acetic acid, and kept for 24 hours. Crystals separate, which consist of pure *m*-4-xylidine acetate. The mother-liquors are treated with hydrochloric acid, and after keeping for 3–4 days, about 20 p.c. of *p*-xylidine separates as hydrochloride. A modification of this process for effecting a complete separation of all the isomerides in commercial xylidine, making use of the method for isolating *m*-4-xylidine as acetate, of *p*-xylidine as hydrochloride (Limpach, Eng. Pat.

11822 of 1886; Fr. Pat. 178616; D. R. P. 39947 of 1886), and of *m*-2-xylydine as formo-*m*-2-xylydide (Limpach, Ber. 1899, 32, 1008), has been described by Hodgkinson and Limpach (Chem. Soc. Trans. 1900, 77, 65). 300 grms. of commercial pure xylydine are treated with slightly more than the necessary amount of glacial acetic acid, or 80 p.c. acetic acid, required to convert the *m*-4-xylydine into its acetate. The amount of acetic acid required can be ascertained approximately by preliminary experiments with a test sample. After keeping for 24 hours the separation of *m*-4-xylydine acetate is practically complete, the yield of the base being 40–42 p.c. of the original xylydine. The crude product is basified with sodium hydroxide and purified by conversion into its formyl-derivative, followed by hydrolysis. To the filtrate and mother-liquors, which contain a considerable amount of *p*-xylydine and smaller quantities of *o*-3-xylydine, *o*-4-xylydine, and *m*-2-xylydine, concentrated hydrochloric acid is added until the whole dissolves. On cooling, practically pure *p*-xylydine hydrochloride separates, the yield of the base being about 30 p.c. of the original xylydine. The residue, containing the two *o*- and the *m*-isomerides, is concentrated in a retort until semi-solid, and when heated gently, *m*-2-xylydine hydrochloride sublimes in silky needle-shaped crystals. The yield of the base, obtained by this method, is 2·7 p.c. of the total xylydine. Another method of obtaining this isomeride when larger quantities are used, is to distil about 20 p.c. of the contents of the retort by heating rapidly; the distillate then solidifies very quickly, and may be purified by conversion into its formyl-derivative. The black residue in the retort, from which *m*-2-xylydine hydrochloride has been sublimed, consists of the hydrochlorides of *o*-3- and *o*-4-xylydine. It is dissolved in water, basified, the bases separated and steam distilled. The distillate, containing 9–11 p.c. of *o*-3-xylydine and 11–14 p.c. of *o*-4-xylydine, is treated with formic acid, and the formyl-derivatives are separated by fractional crystallisation, the *o*-3-isomeride crystallising fairly readily, the *o*-4-isomeride only with difficulty.

When the vapours of the xylydines and methyl alcohol vapour are passed over aluminium oxide at 360°–380°, a mixture of the mono- and dimethyl-derivatives is obtained. Mixtures of α -naphthol or α -naphthylamine and xylydine may be used as a flotation agent, the latter mixture acting as a collector and a frother (Consolidated Copper Mines Co., Chem. Met. Eng. 1919, 21, 418; Robie, Eng. and Min. J. 1919, 108, 730).

***o*-3-Xylydine**, (*o*)-*o*-xylydine, *c*-*o*-xylydine, or β -amino-*o*-xylene; from commercial xylydine (Hodgkinson and Limpach, Chem. Soc. Trans. 1900, 77, 65); by reducing 3-nitro-*o*-xylene with iron filings and acetic acid (Nölting and Forel, Ber. 1885, 18, 2671; Wroblewsky, *ibid.* 2904); by treating 4:5-dibromo-*o*-3-xylydine with sodium amalgam in the cold (Töhl, *ibid.* 2562). A xylydine (acetyl-derivative, m.p. 134°) was obtained by Müller (Ber. 1887, 20, 1039) by heating *o*-4-xylenol with ammonium bromide and zinc-ammonium bromide at 300°, this unexpected result being explained by Müller as due to isomerisation of the *o*-4-xylydine first formed to *o*-3-xylydine. Liquid, b.p. 223°/739

mm., D₄²⁰ 0·991 (N. and F.); b.p. 223·5°/728 mm. (Ullmann, Ber. 1898, 31, 1698); absorption spectrum (Purvis, Chem. Soc. Trans. 1910, 97, 1546). When oxidised with chromic acid mixture, it yields *o*-xyloquinone (N. and F.), whilst on oxidation with lead peroxide it yields azoxylene, m.p. 111°, aminodixylylamine (4-amino-2:3:2':3'-tetramethyldiphenylamine), m.p. 74°–75°, and xyloquinonexylyldi-imine, m.p. 67·5°–68·5° (Goldschmidt, Ber. 1920, 53, 28). By the interaction of *o*-3-xylydine and phthalyl chloride in ethereal solution, *o*-3-xylylphthalimide is obtained together with a yellow substance consisting probably of *aa*-*o*-3-xylylphthalimide and *a*-*o*-3-xylylphthalimide (Kuhara and Comatsu, Mem. Coll. Sci. Eng. Kyōto, 1910, 2, 365). B'HCl+H₂O, large glistening plates (Nölting and Pick, Ber. 1888, 21, 3153), m.p. 254°, b.p. 256°/728 mm., or 258°/760 mm. (Ullmann); B'HNO₃, needles; B'H₂SO₄, large leafy crystals (N. and P.).

Formyl-derivative; m.p. 100°–102° (Hodgkinson and Limpach).

Acetyl-derivative; long fine needles, m.p. 131° (Töhl; Wroblewsky; Jaeger and Blanksma, Rec. trav. chim. 1906, 25, 352), 132° (H. and L.), or 134° (N. and F.).

4:5-Dibromo-*o*-3-xylydine; from 3-nitro-4:5-dibromo-*o*-xylene by reduction with iron and acetic acid (Töhl, Ber. 1885, 18, 2561; Crossley and Smith, Chem. Soc. Trans. 1913, 103, 989). Needles, volatile with steam, m.p. 103°. It does not possess basic properties, and on treatment with sodium amalgam it is converted into *o*-3-xylydine.

4:6-Dibromo-*o*-3-xylydine; by brominating *o*-3-xylydine in glacial acetic acid solution (Jaeger and Blanksma, Proc. K. Akad. Wetensch. Amsterdam, 1905, 8, 153; Rec. trav. chim. 1906, 25, 352). It melts at 56°.

4:5-Dichloro-6-nitro-*o*-3-xylydine; by reducing 3:6-dinitro-4:5-dichloro-*o*-xylene (Claus, &c., J. pr. Chem. 1891, (2) 43, 563). Yellow needles, volatile with steam, m.p. 54°.

The nitro-derivatives of *o*-3-xylydine may be obtained either by nitrating aceto-*o*-3-xylydide, or by the direct nitration of the base at low temperatures in presence of sulphuric acid. In the former case, the separation of the products may be effected by steam distillation, although the process is very tedious, the relative proportions being 30 p.c. of 4-nitro-*o*-3-xylydine, 13 p.c. of 5-nitro-*o*-3-xylydine, and 55 p.c. of 6-nitro-*o*-3-xylydine. The yield obtained by direct nitration of the amine varies, the amount of 5-nitro-*o*-xylydine increasing with the amount of sulphuric acid used. Using 20 parts of sulphuric acid, the yields are 25 p.c. of 4-nitro-*o*-3-xylydine, 45 p.c. of 5-nitro-*o*-3-xylydine, and 30 p.c. of 6-nitro-*o*-3-xylydine (Nölting, Braun and Thesmar, Ber. 1901, 34, 2245).

4-Nitro-*o*-3-xylydine; together with the 5-nitro- and 6-nitro-derivatives by nitrating *o*-3-xylydine sulphate with sulphuric acid and nitric acid at –10°, or, as the acetyl-compounds by a similar nitration of aceto-*o*-3-xylydide (Nölting, Braun and Thesmar; Nölting and Stöcklin, Ber. 1891, 24, 567). Brick-red lozenge-shaped crystals with feebly basic properties.

Acetyl-derivative; colourless needles, m.p. 160°

Benzoyl-derivative; white crystals, m.p. 177°–178° (N., B. and T.).

5-Nitro-o-3-xylylidine; light yellow needles, m.p. 111°–112°. It is more strongly basic than the preceding compound.

Acetyl-derivative; white needles, m.p. 230°–231°.

Benzoyl-derivative; crystals, m.p. 227°–228° (N., B. and T.).

6-Nitro-o-3-xylylidine; brownish-yellow prisms, m.p. 114°.

Acetyl-derivative; faintly yellow needles, m.p. 149°–150°.

Benzoyl-derivative; yellowish crystals, m.p. 208°–209° (N., B. and T.).

4:5-Dinitro-o-3-xylylidine; by heating the acetyl derivative to 90° for 5 minutes with 10 times its weight of sulphuric acid (Crossley and Morrell, Chem. Soc. Trans. 1911, 99, 2345). Orange needles, m.p. 143°.

Acetyl-derivative; by nitrating 5-nitro-aceto-o-3-xylylidine with fuming nitric acid and keeping the mixture at 8°–10° for 1½–2 hours (C. and M.). Colourless needles, m.p. 225°.

5:6-Dinitro-o-3-xylylidine; by hydrolysing the acetyl-derivative with 10 times its weight of sulphuric acid at 110°–115° for 20 minutes (C. and M.). Deep yellow needles, m.p. 172°.

Acetyl-derivative; by nitrating 5-nitro-aceto-o-3-xylylidine with fuming nitric acid and sulphuric acid. White plates, m.p. 180°.

4:6-Dinitro-o-3-xylylidine; by treating 3:4:6-trinitro-o-xylene with alcoholic ammonia (C. and M.; Crossley and Pratt, Chem. Soc. Trans. 1913, 103, 982). Golden-yellow needles, m.p. 161°.

Diacetyl-derivative; fern-like aggregates, m.p. 139°.

o-3-Xylylidine 4-sulphonic acid; by reducing 3-nitro-o-xylene 4-sulphonic acid with ferrous sulphate (Simonsen, Chem. Soc. Trans. 1913, 103, 1144). Octahedral prisms, which blacken but do not melt at 300°. BaA'_2 , rectangular prisms which become pink on exposure to air.

o-3-Xylylidine 5-sulphonic acid; by reducing 3-nitro-o-xylene 5-sulphonic acid with ferrous sulphate (the yield is poor with stannous chloride, owing to the formation of chlorinated products); together with *o-3-xylylidine 6-sulphonic acid*, by sulphonating *o-3-xylylidine* for 2 hours at 160° and then for 1 hour at 180° (S.). Slender needles + 1 (?) H_2O . BaA'_2 , is difficult to crystallise.

o-3-Xylylidine 6-sulphonic acid; bunches of sheaf-like needles, which do not darken at 305°. BaA'_2 , glistening octahedral pyramids, which rapidly effloresce in the air (S.).

Methyl-o-3-xylylidine; by hydrolysing acetyl-methyl-o-3-xylylidine with boiling diluted sulphuric acid for 15 hours (Menton, Ann. 1891, 263, 316). The product, purified by means of the nitroso-derivative, is an oil, b.p. 222°–223°. B'HCl , colourless needles; $\text{B'H}_2\text{SO}_4$; $\text{B}'_2\text{H}_2\text{PtCl}_6$.

Acetyl-derivative; by heating a xylene solution of *o-3-aceto-xylylidine* at 140° with rather more than the theoretical quantity of sodium, and carefully warming the sodium compound produced with methyl iodide (M.). Well-defined crystals, m.p. 75°, volatile with steam. B'HCl , colourless needles; $\text{B'H}_2\text{SO}_4$; $\text{B}'_2\text{H}_2\text{PtCl}_6$.

6-Nitroso-derivative; by treating the nitro-

samine (obtained when the hydrochloride of the base is treated with sodium nitrite in ice-cold aqueous solution) with alcoholic hydrochloric acid. Green needles, m.p. 160°–161°.

When heated with aniline and aniline hydrochloride, the nitroso-derivative yields a red induline (M.).

Ethyl-o-3-xylylidine; obtained from ethyl-aceto-o-3-xylylidine as above (M.). Oil, b.p. 227°–228°. B'HCl , crystals; $\text{B}'_2\text{H}_2\text{PtCl}_6$.

Acetyl-derivative; yellow oil, b.p. about 268°.

p-Nitroso-derivative; green needles, m.p. 123°–124°; hydrochloride, slender yellow needles.

Dimethyl-o-3-xylylidine; together with trimethyl-o-3-xylylidine ammonium iodide by heating *o-3-xylylidine* hydrochloride with the theoretical quantity of methyl alcohol at 180°–190° for 10 hours, and boiling the mixture of methyl- and dimethyl-o-xylylidines formed with methyl iodide for 2–3 hours; the product is treated with soda, and the dimethyl-o-3-xylylidine is distilled with steam (M.). Oil, b.p. 199°–200°. B'HCl , slender needles; $\text{B}'_2\text{H}_2\text{PtCl}_6$, defined needles.

The following alkylamino- and arylamino-derivatives of 4:6-dinitro-o-xylene have been obtained from 3:4:6-trinitro-o-xylene by Crossley and Pratt (Chem. Soc. Trans. 1913, 103, 982): *3-methylamino*-, orange needles, m.p. 90°–91°; *3-dimethylamino*-, orange needles, m.p. 91°–92°; *3-ethylamino*-, stout orange needles, m.p. 75°–76°; *3-anilino*-, bright red plates, m.p. 137°; *3-p-toluidino*-, orange-red plates, m.p. 111°; *3-o-anisidino*-, brick-red needles, m.p. 126°–127°; *3-p-anisidino*-, garnet-coloured flat needles, m.p. 118°; *3-benzylamino*-, orange prisms, m.p. 59°; *3-piperidino*-, orange plates, m.p. 98°.

(a) *o-4-Xylylidine*, *i-o-xylylidine*; from commercial xylylidine (Hodgkinson and Limpach, Chem. Soc. Trans. 1900, 77, 65); by reducing 4-nitro-o-xylene with tin and hydrochloric acid (Jacobsen, Ber. 1884, 17, 160); by heating *m*-toluidine hydrochloride with methyl alcohol at 250° (Limpach, Ber. 1888, 21, 646); by reducing ω (2)-chloro-4-nitro-o-xylene with tin and hydrochloric acid (Stephen, Short and Gladding, Chem. Soc. Trans. 1920, 117, 510); by heating *o*-xylene for several hours with hydroxylamine hydrochloride and aluminium chloride (Graebe, Ber. 1901, 34, 1778). Vitreous rhombic tables, or large monoclinic crystals, m.p. 49°, b.p. 226°, D_{20}^{25} 1.0755 (J.); b.p. 224°/728 mm. (Ullmann, Ber. 1898, 31, 1698); m.p. 50° (Jaeger and Blanksma, Rec. trav. chim. 1906, 25, 352), or m.p. 52° (Hodgkinson and Limpach), not coloured on exposure to air and light. It gives no colour with bleaching powder, and its solutions colour pine-wood yellow. On heating the hydrochloride with methyl alcohol at 300°–320°, it yields pseudocumidine (Nöling and Forel, Ber. 1885, 18, 2680). When oxidised together with diamino-diphenylamine a safranine is formed (Nietzki, Ber. 1886, 19, 3163). $\text{B'HCl} + \text{H}_2\text{O}$, long thin prisms (J.), m.p. 266°, b.p. 264°/728 mm., or 266°/760 mm. (Ullmann); B'HNO_3 ; $\text{B}'_2\text{H}_2\text{SO}_4$ (Nöling and Pick, Ber. 1888, 21, 3153).

Formyl-derivative; m.p. 52°.

Acetyl-derivative; m.p. 99°.

5-Chloro-o-4-xylylidine; glistening leaflets.

which sublime, m.p. 86° (Claus, J. pr. Chem.

Acetyl-derivative; colourless slender prisms, m.p. 154°, is formed by heating the oxime of 5-chloro-o-xylyl-4-methyl ketone with sulphuric acid (Claus).

3:5-Dichloro-o-4-xylidine; by the hydrolysis of its acetyl-derivative, obtained by dichlorinating o-4-acetoxylidide (Crossley, Chem. Soc. Trans. 1904, 85, 264). Long glistening silky needles, m.p. 44.5°.

6-Bromo-o-4-xylidine; by reducing 3-bromo-5-nitro-o-xylene with stannous chloride (Crossley and Bartlett, Chem. Soc. Trans. 1913, 103, 1297). Silky needles, m.p. 82°.

Acetyl-derivative; small transparent plates, m.p. 205°-206°; *diacetyl-derivative*, four-sided plates, m.p. 109° (C. and B.).

3:5-Dibromo-o-4-xylidine; by brominating o-4-xylidine in glacial acetic acid solution (Jaeger and Blanksma, Proc. K. Akad. Wetensch. Amsterdam, 1905, 8, 153; Rec. trav. chim. 1906, 25, 352). It melts at 63°.

3:6-Dibromo-o-4-xylidine; by successive bromination and hydrolysis of aceto-o-4-xylidide. Crystals, m.p. 65° (J. and B.).

o-4-Xylidine on nitration yields three mono-nitro-derivatives, the relative proportions when the nitration is carried out in presence of sulphuric acid being 47 p.c. of 5-nitro-o-4-xylidine, 31 p.c. of 3-nitro-o-4-xylidine, and 13 p.c. of 6-nitro-o-4-xylidine (Nölting, Braun and Thesmar).

3-Nitro-o-4-xylidine; together with the 5-nitro- and 6-nitro-derivatives by nitrating o-4-xylidine with nitric acid and sulphuric acid at -15° (Nölting, Braun and Thesmar, Ber. 1901, 34, 2248; cf. Nölting and Stöcklin, *ibid.* 1891, 24, 564). Scarlet-red prisms, m.p. 65°-66°. Readily volatile with steam and more strongly basic than the 5-nitro-derivative.

Acetyl-derivative; small white needles, m.p. 115°-116°, is also formed by reducing 3:4-dinitro-o-xylene with stannous chloride and heating the product for 2 hours with acetyl chloride (Crossley and Morrell, Chem. Soc. Trans. 1911, 99, 2345); *benzoyl-derivative*, small white needles, m.p. 199°-200°.

5-Nitro-o-4-xylidine; brownish-red prisms, m.p. 139°-140°; is also obtained by heating 5-nitro-o-4-xylol with ammonia and ammonium chloride for 20 hours at 140°-150° (Diepolder, Ber. 1909, 42, 2916); its salts are decomposed by water.

Acetyl-derivative; small light yellow needles, m.p. 117°; *benzoyl-derivative*, light yellow silky needles, m.p. 149°-150° (N., B. and T.).

6-Nitro-o-4-xylidine; long lustrous orange-coloured plates, m.p. 74°-75°, less volatile with steam than the 3- and 5-nitro-derivatives.

Acetyl-derivative; by nitrating aceto-o-4-xylidide with nitric acid (D 1.42) and sulphuric acid (Crossley and Morrell, Chem. Soc. Trans. 1911, 99, 2345) or by acetylating the amine. Small white needles, m.p. 209°-210°; *benzoyl-derivative*, small white needles, m.p. 223°-224°.

3:5-Dinitro-o-4-xylidine; by the action of alcoholic ammonia on 3:4:5-trinitro-o-xylene (Crossley and Morrell, Chem. Soc. Trans. 1911, 99, 2345; Crossley and Pratt, *ibid.* 1913, 103, 982). Orange-red needles, m.p. 143° (C. and B.).

Acetyl-derivative; by nitrating 3-nitro-aceto-o-4-xylidide with a mixture of nitric and sulphuric acids at -2° (C. and M.), or by nitrating aceto-o-4-xylidide with fuming nitric acid at -5° (C. and M.). Transparent needles, m.p. 223°.

5:6-Dinitro-o-4-xylidine; by hydrolysing the acetyl-derivative with 10 times its weight of concentrated sulphuric acid for 10 minutes at 110° (C. and M.). Deep orange-red needles, m.p. 212°.

Acetyl-derivative; by nitrating aceto-o-4-xylidide with nitric acid (D 1.5) and sulphuric acid; by the further nitration of 6-nitro-aceto-o-4-xylidide with fuming nitric acid (C. and M.). Fine white needles, m.p. 173°.

o-4-Xylidine 5-sulphonic acid; by reducing 4-nitro-o-xylene 5-sulphonic acid with alkaline ferrous sulphate; together with o-4-xylidine 6-sulphonic acid by sulphonating o-4-xylidine, or *s*-dixylylcarbamide (Simonsen, Chem. Soc. Trans. 1913, 103, 1144). Tablets, which blacken at 280°, but do not decompose at 300°. $\text{BaA}'_2 + 8\text{H}_2\text{O}$, rectangular plates or spangles.

o-4-Xylidine 6-sulphonic acid; see above. Plates $+2\text{H}_2\text{O}$ (?), which do not readily redden on exposure to air. It darkens at 283°, and melts at 294° with decomposition. $\text{BaA}'_2 + 1\frac{1}{2}\text{H}_2\text{O}$, large orthorhombic (?) plates, which become pink (S.). The same (?) acid is obtained by heating dixylylcarbamide with sulphuric acid (D 1.71) at 150°-160° (Cazeneuve and Moreau, Bull. Soc. chim. 1898, (3) 19, 21).

Dimethyl-o-4-xylidine; by heating a toluene solution of o-4-xylidine with dimethyl sulphate for 3 hours on the water-bath (Bielecki and Koleniew, Anzeiger Akad. Wiss. Krakau, 1908, 296); by distilling the quaternary ammonium hydroxide (E. Fischer and Windaus, Ber. 1900, 33, 351). It boils at 232° (F. and W.), or at 225°-227° (B. and K.). The ammonium iodide forms prisms, decomposing at 235°-237°. The following alkylamino- and arylamino-derivatives of 3:5-dinitro-o-xylene have been prepared by the action of ammonia and various amines on 3:4:5-trinitro-o-xylene (Crossley and Pratt, Chem. Soc. Trans. 1913, 103, 972): 4-methylamino-, stout scarlet plates, m.p. 143°; 4-di-methylamino-, orange-red needles, m.p. 103°-104°; 4-ethylamino-, orange-red needles, m.p. 115°; 4-anilino-, orange-red needles, m.p. 134°; 4-p-toluidino-, fine orange needles, m.p. 133°; 4-o-anisidino-, stout crimson-lake needles, m.p. 138°-139°; 4-p-anisidino-, bright crimson needles, m.p. 131°; 4-benzylamino-, orange plates, m.p. 128.5°.

The following diamines are prepared by reducing the corresponding nitro-o-3- and o-4-xylidines (Nölting, Braun and Thesmar, Ber. 1901, 34, 2242; Nölting and Thesmar, *ibid.* 1902, 35, 628).

3:4-Diamino-o-xylene; white quadratin plates, m.p. 89°.

Diacetyl-derivative; small white needles, m.p. 196°-197°.

3:5-Diamino-o-xylene; small white needles, m.p. 68°-67°.

Diacetyl-derivative; small white needles, m.p. 240°-241°.

3:6-Diamino-o-xylene; thick pale yellow needles, m.p. 116°, is obtained also by reducing the azo-dye obtained from o-3-xylidine and

diazobenzene sulphonio acid with tin and hydrochloric acid.

Diacetyl-derivative; small white needles, m.p. 275°–276°.

4:5-Dichloro-derivative; needles which sublime, m.p. 176° (Claus and Berkefeld, J. pr. Chem. 1891, (2) 43, 583). The dichloro-diamine on oxidation with chromic acid yields 4:5-dichloro-*o*-xylo-3:6-quinone, m.p. 159°, which sublimes in thin yellow leaflets (C. and B.).

4:5-Diamino-o-xylene; white plates, m.p. 125°–126° (anhydrous).

Diacetyl-derivative; m.p. 227°–228°.

A table differentiating the diamines by their behaviour with ferric chloride, potassium dichromate, sodium nitrite, and bleaching powder is given by Nölting and Thesmar (*l.c.*).

m-2-Xylidine, *v-m-xylidine*, *c-m-xylidine*, or *β-xylidine*; by distilling 2-amino-mesitylenic acid with lime (Schmitz, Ann. 1878, 193, 179); from commercial xylidine (Nölting and Pick, Ber. 1888, 21, 3150; cf. Wroblewsky, Ber. 1879, 12, 1226; Ann. 1881, 207, 91; Noyes, Amer. Chem. J. 1898, 20, 789; Hodgkinson and Limpach, Chem. Soc. Trans. 1900, 77, 65; Winkelhausen, D. R. P. 251334 of 1911); by reducing 2-nitro-*m*-xylene (Grevink, Ber. 1884, 17, 2430; Nölting and Förel, Ber. 1885, 18, 2668; Bull. Soc. chim. 1884, (2) 42, 332, 338; Miolatti and Lotti, Gazz. chim. ital. 1897, 27, i. 293; Busch, Ber. 1899, 32, 1008). Liquid, b.p. 214°/739 mm. (N. and F.); b.p. 211°–212° (B.); b.p. 216°/735 mm., D_{15}^{20} 0.980 (H. and L.). Absorption spectrum (Purvis, Chem. Soc. Trans. 1910, 97, 1546). $B'HCl + \frac{1}{2}H_2O$, needles which sublime; $B'HN O_3$, needles; $B'H_2SO_4 + 2\frac{1}{2}H_2O$ (N. and P.).

Formyl-derivative; very long needles, m.p. 164°, or 176°–177° when heated rapidly (H. and L.); *acetyl-derivative*, needles, m.p. 174° (G.), or m.p. 177° (H. and L.); *benzoyl-derivative*, silky needles, m.p. 164° (Friedländer and Brand, Monath. 1898, 19, 627), or m.p. 159°–160° (B.); *benzylidene-derivative*, yellow oil (B.); *m-nitro-benzylidene-derivative*, yellow crystals, m.p. 105°; *o-nitro-benzylidene-derivative*, reddish-brown crystals; *o-hydroxy-benzylidene-derivative*, yellow oil (B.). When oxidised, *m-2-xylidine* is converted into *m*-xyloquinone (N. and F.). The hydrochloride when heated with methyl alcohol at 300°–320° yields mesidine. The base condenses with formaldehyde in presence of hydrochloric acid, forming diaminodixylylmethane, m.p. 126°, and with *p*-nitro-benzaldehyde forming *p*-nitro-diaminophenyldixylylmethane, yellow prisms, m.p. 136° (F. and B.). By the Sandmeyer reaction *m-2-xylidine* yields 2-cyano-*m*-xylene, white prisms which sublime, m.p. 89° (N.). Acetyl-*m-2-xylidyl-nitrosamine* is obtained by the action of nitrous acid on aceto-*m-2-xylidide* and forms yellow plates, m.p. 62°–63°, which are converted into 7-methylindazole, m.p. 138°, and acetic acid by boiling with benzene (Jacobson and Huber, Ber. 1908, 41, 660). Aceto-*m-2-xylidide* is oxidised by potassium permanganate in presence of magnesium sulphate to 2-acetylaminophthalic acid (Nölting and Gachot, Ber. 1906, 39, 73).

4:6-Dichloro-m-2-xylidine (?); from the corresponding nitro-dichloro-xylene by reduction with stannous chloride, hydrochloric acid, and alcohol. Colourless needles which soon

become coloured, m.p. 85° (Claus and Runschke, J. pr. Chem. 1890, (2) 42, 110). B', H_2PtCl_6 , brown powder.

4-Bromo-m-2-xylidine; by reducing 4-bromo-2-nitro-*m*-xylene (Nölting, Braun and Thesmar, Ber. 1901, 34, 2242). Lustrous colourless needles, m.p. 21.5°, b.p. 146°–147°/15 mm. (N., B. and T.; cf. E. Fischer and Windaus, Ber. 1900, 33, 1967).

Acetyl-derivative; small needles, m.p. 136°, preferably prepared indirectly from 4-nitroaceto-*m-2-xylidide*, by reduction and replacement of the amino-group by bromine (N., B. and T.).

5-Bromo-m-2-xylidine; by brominating *m-2-xylidine* in glacial acetic acid (N., B. and T.); by brominating *m-2-xylidine* in presence of a large excess of hydrochloric acid or hydrobromic acid and treating the N-halogen derivative with hydrochloric acid (F. and W.). Prisms or lot white needles, m.p. 49°–50° (F. and W.), m.p. 50°–51° (N., B. and T.).

Acetyl-derivative; small white needles, m.p. 193°–194° (N., B. and T.), or 197° (corr.) (F. and W.). *m-2-Aceto-m-xylidide* on bromination yields a mixture of 4- and 5-bromo-derivatives.

4:5-Dibromo-m-2-xylidine; by warming a mixture of 4-bromo-*m-2-xylidine* with bromine in presence of hydrobromic acid (Jaeger and Blankema, Rec. trav. chim. 1906, 25, 352; Proc. K. Akad. Wetensch. Amsterdam, 1905, 8, 153). Crystals, m.p. 51°.

4:6-Dibromo-m-2-xylidine; by reducing 4:6-dibromo-2-nitro-*m*-xylene with iron and acetic acid (Auwers and Traun, Ber. 1899, 32, 3309); from *m*-xylene by bromination, nitration, reduction, and diazotisation (J. and B.). Fine felted needles, m.p. 99°–100° (A. and T.), or m.p. 120° (J. and B.).

4:5:6-Tribromo-m-2-xylidine; by brominating 4:6-dibromo-*m-2-xylidine* in acetic acid solution (J. and B.). Colourless crystals, m.p. 197°.

4-Nitro-m-2-xylidine; by nitrating *m-2-xylidine* with a mixture of nitric and sulphuric acids at 0° in presence of a little urea (Nölting and Stöcklin, Ber. 1891, 24, 564). Sulphur-coloured needles, m.p. 81°–82° (N. and S.).

Acetyl-derivative; from the nitroamine; by nitrating *m-2-acetoxylidide* dissolved in 5 parts of sulphuric acid with 1 mol. of nitric acid (97–98 p.c.) (N. and S.). Long white needles, m.p. 170° (N. and S.), or 167°–168° (N., B. and T.).

5-Nitro-m-2-xylidine; in low yield by heating 2:5-dinitro-*m*-xylene with methyl alcoholic ammonia for 32 hours at 200° (Ibbotson and Kenner, Chem. Soc. Trans. 1923, 123, 1260). Orange-yellow needles, m.p. 158°.

Acetyl-derivative; m.p. 178°.

4:6-Dinitro-m-2-xylidine; by the hydrolysis of the acetyl-derivative obtained by nitrating aceto-*m-2-xylidide* with 2 parts of nitric acid and 10 parts of sulphuric acid at 0° (N. and S.). Yellow needles, m.p. 177° (N. and S.), or small yellow leaflets, m.p. 174°–175° (N. and T.).

Acetyl-derivative; white needles, m.p. 225°–226° (N. and S.), or 226°–228° (decomp.) (Nölting and Thesmar, Ber. 1902, 35, 628).

Methyl-m-2-xylidine; by the action of methyl iodide on *m-2-xylidine* (Friedländer and Brand, Monath. 1898, 19, 627). Colourless

oil with an odour of camphor, volatile with steam, b.p. 207°. It does not react with aldehydes, nitrous acid, or diazonium compounds. $B_2H_3PtCl_6$, long yellow needles.

Acetyl-derivative; tables, m.p. 94°–95°, volatile with steam.

Dimethyl-m-2-xylydine; by the action of excess of methyl iodide and sodium hydroxide on *m-2-xylydine* for 5 hours at 130° under pressure (F. and B.). Oil, b.p. 195°–196° (F. and B.); E. Fischer and Windaus, Ber. 1900, 33, 345), with similar properties to the preceding compound. $B_2H_3PtCl_6$, yellow needles.

Ethyl-m-2-xylydine; colourless liquid of camphoraceous odour, b.p. 217°–218° (F. and B.). $B_2H_3PtCl_6$, prisms.

Diethyl-m-2-xylydine; colourless oil of camphoraceous odour, volatile with steam, b.p. 220°–221° (F. and B.). $B_2H_3PtCl_6$, small needles.

m-4-Xylydine, as-*m-xylydine*, *i-m-xylydine*, or α -xylydine; by treating *m-xylene* with hydroxylamine hydrochloride in presence of aluminium chloride (Graebe, Ber. 1901, 34, 1778); by reducing 4-nitro-*m-xylene* with iron and acetic acid (Deumelandt, Ann. 1867, 144, 273; Zeit. für Chem. 1866, 2, 21; Grevingk, Ber. 1884, 17, 2430; Tawildarow, Zeit. für Chem. 1870, 6, 418; Ber. 1869, 2, 553; Wallach, Ann. 1890, 258, 331; Wroblewsky, Ann. 1878, 192, 215; 1881, 207, 91); by heating aniline hydrochloride, *o*- and *p*-toluidine hydrochlorides with methyl alcohol at 250°–300° (Hofmann, Ber. 1876, 9, 1295; Limpach, Ber. 1888, 21, 640); by distilling (4:3:1:5)-amino-mesitylenic acid with lime (Schmitz, Ann. 1878, 193, 177); by heating *m-4-xylenol* with zinc ammonium bromide and ammonium bromide (Müller, Ber. 1887, 20, 1041); by the hydrolysis of its sulphonic acid with hydrochloric acid (Limpach, Ber. 1887, 20, 871); from commercial xylydine (Hodgkinson and Limpach, Chem. Soc. Trans. 1900, 77, 65; M. L. B., D. R. P. 87615 of 1895). Liquid, b.p. 215.8°–216°/728 mm. (Ullmann), b.p. 212°, D^{20}_D 0.9184 (H.), b.p. 216°, D^{18}_D 0.985 (T.). $BHCl$, monoclinic prisms (S.), tables or leaflets + $\frac{1}{2}H_2O$ (Städel and Hölz, Ber. 1885, 18, 2920), m.p. 235°, b.p. 253.1°/728 mm., or 255.1°/768 mm. (Ullmann, Ber. 1898, 31, 1699); $BHBr$, tables or columns (Städel, Ber. 1883, 16, 28; 1885, 18, 2920), or trimetric crystals (Bertram, Jahresberichte, 1882, 386); $BHNO_3$, rhombic tables; $B_2H_3SO_4 + 4\frac{1}{2}H_2O$, cubes (S. and H.; Nölting and Pick, Bull. Soc. chim. 1888, (2), 50, 606); $B_2H_3PO_4$ (Lewy, Ber. 1886, 19, 2728), colourless needles, m.p. 172° (Lemoult, Compt. rend. 1906, 142, 1193); $B_2H_3Br_2$ (Fries, Ber. 1904, 37, 2338; Ann. 1906, 346, 128); $B_2H_3C_2O_4$, m.p. 167° (Anselmino, Ber. Deut. pharm. Ges. 15, 422); telluribromide, small glistening plates (Guthier, &c., J. pr. Chem. 1912, (2) 86, 150); B_2ZnCl_4 (Lachovitch, Monatsch. 1888, 9, 514); $B_2HgH_2(SO_4)_2 + H_2O$; $B_2Cu_2H_2(SO_4)_2$ (Deniges, Compt. rend. 1890, 112, 870); $B_2H_3ZnCl_4$ (Tombeck, Ann. Chim. Phys. 1900, (7) 21, 438); $B_2H_3ZnBr_4$; $B_2H_3CdCl_4$; $B_2H_3CdBr_4$; $B_2H_3ZnI_4$; $B_2H_3CdI_4$; B_2ZnBr_4 (Tombeck, Ann. Chim. Phys. 1900, (7) 21, 408); B_2ZnI_4 ; $B_2Zn(NO_3)_4$; B_2CdCl_4 ; B_2CdBr_4 ; B_2CdI_4 ; $B_2Cd(NO_3)_4$; B_2CdSO_4 ; B_2AgNO_3 ; $B_2Ag_2SO_4$; see also Leeds (Jahresberichte,

1882, 504). $B_2C_2H_3SO_4H$, needles, m.p. 129.5° (Hälsig, J. pr. Chem. 1897, (2) 56, 218). $B_2C_2H_3(NO_3)_4$, reddish-brown crystals, m.p. 96°–98° (Nölting and Sommerhoff, Ber. 1906, 39, 76); $B_2C_2H_3(CH_3)(NO_2)_2$, red crystals, m.p. 43°–45°; $B_2C_2H_3OH$, m.p. 16° (Kremann, Monatsch. 1906, 27, 91). *Formyl-derivative*, needles or leaflets, m.p. 113°–114° (Hodgkinson and Limpach; Gasiorowski and Merz, Ber. 1885, 18, 1011); or m.p. 111° (Gudemann, Ber. 1888, 21, 2549); *acetyl-derivative* (Auwers, J. pr. Chem. 1881, 23, 456), m.p. 129°–130° (Nölting and Forel, Ber. 1885, 18, 2677; Städel and Hölz, or m.p. 127°–128° (Willgerodt and Schmierer, *ibid.* 1904, 38, 1472; Töhl, Ber. 1885, 18, 359; Hofmann, Ber. 1876, 9, 1297; Wroblewsky, Ann. 1881, 207, 91), or 120° (Graebe); *diacetyl-derivative*, crystals, m.p. 60° (Wallach, Ann. 1890, 258, 330); *phenyl-derivative*, m.p. 157°–158° (S. and H.); *benzoyl-derivative*, needles, m.p. 192° (Hübner, Ann. 1881, 208, 318), or 187°–189° (Gudemann, Ber. 1888, 21, 2549); *benzylidene-derivative*, oil, b.p. above 300° (Michaelis, Ann. 1893, 274, 200).

When *m-4-xylydine* is heated with potassium ethyl oxalate at 180°–190°, oxalxylydic acid, $C_8H_8NHCOCOOH$, needles + H_2O , m.p. 128°–129°, is obtained. On heating, this acid forms oxalxylydide, flat needles, m.p. 210° (Mauthner and Suida, Monatsch. 1888, 9, 736). *m-4-Xylydine* forms a carbamate, m.p. 57°, a cyanate, b.p. 205°, and a cyanurate, m.p. 162° (Frentzel, Centralblatt, 1888, 1361). The *acetyl-derivative* of *m-4-xylydine*, when heated with phosphorus pentasulphide, is converted into thioaceto-*m-4-xylydide*, m.p. 94°–95° (Jacobsen and Ney, Ber. 1889, 22, 904; Gudemann, Ber. 1888, 21, 2551). When treated with paraldehyde in presence of hydrochloric acid, *m-4-xylydine* forms dimethylquinaldine, m.p. 146°, b.p. 260°/719 mm., readily volatile with steam (Panajotow, Ber. 1887, 20, 32). Diamino-dimethylstilbene sulphide is obtained by heating *m-4-xylydine* with $\frac{1}{2}$ of its weight of sulphur at 185°–195°, until the evolution of hydrogen sulphide ceases (Anschütz and Schultz, Ber. 1889, 22, 580).

m-4-Xylydine may be converted by the Sandmeyer reaction into 4-iodo-*m-xylene*, which on treatment with concentrated sulphuric acid and keeping for about 5 weeks yields a mixture of 4-iodo-*m-xylene* 6-sulphonic acid and a diiodo-*m-xylene* (Hammerlich, Ber. 1890, 23, 1634). *m-4-Xylydine* forms the nitrile, $C_8H_7(CH_3)_2CN$, m.p. 23°–24°, which on treatment with hydroxylamine for 5 to 6 hours, at 80°–85°, is converted into xylenylamidoxime, colourless needles, m.p. 178° (Oppenheimer, Ber. 1889, 22, 2242). Aceto-*m-4-xylydide*, when heated with an equal weight of sodium ethoxide in the absence of air at 250°–300°, followed by addition of water and distillation with steam, yields 2:5-dimethyl-indole, m.p. 114°, whilst the free base on treatment with succinic anhydride yields 2:4-xylylsuccinamic acid, m.p. 164° (Salway, Chem. Soc. Trans. 1913, 103, 1988; Raschen, Ann. 1887, 239, 227).

With phosphorus pentachloride *m-4-xylydine* forms the chloride, $PCl(NH-C_8H_7)_2$, m.p. 264° (decomp.); the corresponding nitrate, $P(NH-C_8H_7)_2NO_3$, forms silky needles, m.p. 246°–248° (Lemoult, Compt. rend. 1904, 139,

185). *m*-4-Xylidine nitrite is obtained by treating *m*-4-xylidine hydrochloride in concentrated aqueous solution with alkaline sodium nitrite (Wallach, Ann. 1907, 353, 318). When acetaldehyde is added to a solution of *m*-4-xylidine in dilute hydrochloric acid and the mixture is kept for 24 hours, condensation occurs, and a mixture of 2-isomeric substances, $C_8H_9(CH_3)_2NHCH(CH_3)CH_2CHO$, is eventually obtained (Miller, Plöchl and Mozdzyński, Ber. 1896, 29, 1462). The derivatives and relationship of these substances have been described and re-examined by Edwards, Garrod and Jones (Chem. Soc. Trans. 1912, 101, 1376). With iodine monochloride, *m*-4-xylidine yields 5-iodo-*m*-4-xylidine, m.p. 65°, and when 2 mols. of iodine chloride are used the iodo-derivative is accompanied by a small quantity of 3:5:3':5'-tetramethyl-2:2'-diaminodiphenyl, m.p. 180° (Kerschbaum, Ber. 1895, 28, 2798). By heating 1 part of *m*-4-xylidine with 4 parts of sulphur and 1 part of aniline at 200°–240°, an isomeric derivative of dehydrothio-*p*-toluidine is obtained (Green and Jansen, Eng. Pat. 4448 of 1895). When *m*-4-xylidine is kept in contact with acetylbenziminio-ethylether and the acetyl-group is then hydrolysed, *m*-4-xylidylbenzamine, m.p. 106°, is formed (Wheeler and Walden, Amer. Chem. J. 1898, 20, 568). Treatment of *m*-4-xylidine with chloroacetic acid in ethereal solution yields *α*-*m*-xylidylglycine, m.p. 133° (Ehrlich, Ber. 1883, 16, 204). *m*-4-Xylidine hydrochloride is converted into mesidine by heating with methyl alcohol at 250°–300° (Limpach, Ber. 1888, 21, 640, 643). *m*-4-Xylidine, heated with a mixture of ethylene dibromide and sufficient sodium carbonate to neutralise the hydrogen bromide evolved, is converted into di-*m*-xylidylethylenediamine, feathery needles, m.p. 74°–75° (Senior and Goodwin, Chem. Soc. Trans. 1901, 79, 254). *as*-*m*-4-Xylidylphthalimide, yellow needles, m.p. 142°–143°, *m*-4-xylidylphthalimide, silky needles, m.p. 202°–203°, and *s*-*m*-4 xylidylphthalimide, m.p. 154°, are formed by the interaction of phthalyl chloride and *m*-4-xylidine in ethereal solution. The first named substance is converted by mineral acids or alkalis into *s*-*m*-xylidylphthalimide (Kuhara and Komatsu, Mem. Coll. Sci. Eng. Kyōto, 1910, 2, 365).

5-Chloro-m-4-xylidine; by the hydrolysis of its acetyl-derivative (Orton and King, Chem. Soc. Trans. 1911, 99, 1185). Feathery needles, volatile with steam, m.p. 37°–38° (O. and K.), or 40°–41° (Bamberger and Reber, Ber. 1913, 46, 800).

Acetyl-derivative; by treating aceto-*m*-4-xylidine in glacial acetic acid solution with 1 equivalent of acetylchloroamino-2:4-chlorobenzene in acetic acid and $\frac{1}{10}$ gram molecular proportion of hydrochloric acid for 70 hours in the dark. The mixture is then diluted to 50 p.c. acetic acid, and kept for 3 days, when the major portion of the 2:4-dichloroacetanilide separates. Finally the mother liquor is diluted to 5 p.c. acetic acid, and extracted with chloroform (O. and K.). Short prisms, m.p. 196°–5°–197°–5°.

6-Chloro-m-4-xylidine; by reducing 6-nitro-4-chloro-*m*-xylene with tin and hydrochloric acid (Bamberger and Reber, Ber. 1913, 46, 787); by the action of concentrated hydro-

chloric acid on *m*-xylidyl-4-hydroxylamine (Cadgène, Dissertation, Zürich, 1903, 61). Leaflets, m.p. 98°–99°, readily volatile with steam.

Acetyl-derivative; silky needles, m.p. 158°–5° (B. and K.).

Chloro-m-4-xylidine; together with *m*-4-xylidine by reducing 4-nitro-*m*-xylene with tin and hydrochloric acid (Tawildarow, Zeit. für Chem. 1870, 6, 419). Crystals, m.p. 89°.

2:5:6-*Trichloro-m-4-xylidine*; by treating aceto-*m*-4-xylidide with nitric acid (D 1398) and hydrochloric acid (D 119) and then hydrolysing the acetyl-group (Mannino and Donato, Gazz. chim. ital. 1908, 38, ii. 20). Crystals, m.p. 203°.

Acetyl-derivative; white needles, m.p. 192°.

2-*Bromo-m-4-xylidine*; by reducing 2-bromo-4-nitro-*m*-xylene (Nölting, Braun and Thesmar, Ber. 1901, 34, 2242). Colourless silky needles, m.p. 47°–48°.

Acetyl-derivative; small colourless needles, m.p. 151°–152° (N., B. and T.; Fries, Ann. 1906, 346, 128).

p-*Nitrobenzylidene derivative*; small yellow needles, m.p. 182°–183°.

5-*Bromo-m-4-xylidine*; by brominating *m*-4-xylidine in acetic acid solution (N., B. and T.; cf. Vaubel, J. pr. Chem. 1896, (2) 53, 549); by reducing 5-bromo-4-nitro-*m*-xylene (N., B. and T.); from 4-nitro-*m*-5-xylidine by the Sandmeyer reaction, followed by reduction (N., B. and T.); by brominating *m*-4-xylidine in presence of a large excess of cold hydrochloric acid or hydrobromic acid and treating the yellowish-red crystalline mass with warm hydrochloric acid (E. Fischer and Windaus, Ber. 1900, 33, 1967; Fries, Ber. 1904, 37, 2338; Ann. 1906, 346, 128). Prisms, m.p. 45° [V.], or 46°–47° (F. and W.), or colourless silky needles, m.p. 47°–48° (N., B. and T.).

Acetyl-derivative; by acetylating the base. Prisms or needles, m.p. 193° [V.], or 196°–197° (F. and W.). When aceto-*m*-4-xylidide is brominated, however, an isomeric bromoacetyl-*m*-4-xylidide, m.p. 95°–96°, is obtained [V.]; *diacetyl-derivative*, prisms, m.p. 59°.

p-*Nitrobenzylidene-derivative*; yellow needles, m.p. 130°.

6-*Bromo-m-4-xylidine*; by reducing 6-nitro-4-bromo-*m*-xylene (N., B. and T.; Bamberger and Reber, Ber. 1913, 46, 787); as the main product of the bromination of *m*-4-xylidine in presence of concentrated sulphuric acid (Fries). White plates, volatile with steam, m.p. 99°–100° (N., B. and T.), or m.p. 96° (Jaeger and Blankens, Rec. trav. chim. 1907, 25, 352; Proc. K. Akad. Wetensch. Amsterdam, 1905, 8, 153; Genz, Ber. 1870, 3, 225).

Acetyl-derivative; plates, m.p. 168°–169° (N., B. and T.); *diacetyl-derivative*, plates, m.p. 70° (Fries, Ann. 1906, 346, 128).

p-*Nitrobenzylidene derivative*; yellow needles, m.p. 130° (N., B. and T.).

2:6-*Dibromo-m-4-xylidine*; by the hydrolysis of the acetyl-derivative (J. and B.). Crystals, m.p. 65°.

Acetyl-derivative; together with a mono-bromo-aceto-*m*-4-xylidide by brominating aceto-*m*-4-xylidide (J. and B.).

5:6-*Dibromo-m-4-xylidine*; from 6-bromo-*m*-4-xylidine by the action of bromine in presence

of hydrochloric acid (J. and B.), rather than from 5-bromo-*m*-4-xyldine (Fries, Ann. 1906, 346, 128). Needles, m.p. 38° (J. and B.), or m.p. 40° (F.).

Acetyl-derivative; needles, m.p. 192° (F.); *diacetyl-derivative*, prisms, m.p. 183° (F.).

2:5:6-*Tribromo-m-4-xyldine*; by the hydrolysis of the acetyl-derivative, m.p. 246°–248°, obtained by boiling aceto-*m*-4-xyldide with nitric acid (D 1398) and hydrobromic acid (D 148) (Mannino and Donato, Gazz. chim. ital. 1908, 38, ii. 20).

Methyl-m-4-xyldine; by heating *m*-4-xyldine hydrochloride with methyl alcohol, for 7 hours at 170°–180°, treating the crude product with sodium nitrite and hydrochloric acid, and reducing the nitrosoamine with tin and hydrochloric acid (Pinnow and Oesterreich, Ber. 1898, 31, 2926). Oil, b.p. 220.5°–221.5°/760 mm.

N-Nitroso-derivative; an uncrystallisable oil.

Acetyl-derivative; fine white needles and thick prisms, m.p. 65° (P. and O.).

Dimethyl-m-4-xyldine; by heating *m*-4-xyldine with dimethyl sulphate at 200° (Bielecki and Koleniew, Anzeiger Akad. Wiss. Krakau, 1908, 296); by heating *m*-4-xyldine hydrobromide with methyl alcohol (Baur and Städel, Ber. 1883, 16, 32); by distilling the quaternary hydroxide (E. Fischer and Windaus, Ber. 1900, 33, 345). Oil, b.p. 203° (F. and W.), or 203°–205° (B. and S.); *methiodide*, m.p. 183° (decomp.); *methochloride* is hygroscopic (F. and W.).

5-Bromo-dimethyl-*m*-4-xyldine; oil, b.p. 246°–247°/759 mm. (E. Fischer and Windaus, Ber. 1900, 33, 1967). $B'H_2PtCl_6$, yellowish-red lanceolate crystals.

2-Nitro-*m*-4-xyldine; by reducing 2:4-dinitro-*m*-xylene with hydrogen sulphide in alcoholic ammoniacal solution; in small quantity by treating *m*-4-xyldine with a mixture of nitric and sulphuric acids (Grevingk, Ber. 1884, 17, 2425, 2428; Nölting, Braun and Thesmar, Ber. 1901, 34, 2242). Golden-yellow needles, m.p. 78° (G.), or 81°–82° (N., B. and T.).

Acetyl-derivative; white needles, m.p. 149° (G.), or 147° (Blanksma, Rec. trav. chim. 1909, 28, 92); *benzoyl-derivative*, white silky needles, m.p. 236° (Errera and Maltese, Gazz. chim. ital. 1903, 33, ii. 277).

5-Nitro-*m*-4-xyldine; by nitrating aceto-*m*-4-xyldide and hydrolysing the product (Hofmann, Ber. 1876, 9, 1292; Wroblewsky, Ann. 1881, 207, 91; Nölting and Collin, Ber. 1884, 17, 261; Töhl, Ber. 1885, 18, 359; Nölting and Forel, Ber. 1885, 18, 2068; Gabriel and Stelzner, Ber. 1896, 29, 303; Willgerodt and Schmierer, Ber. 1905, 38, 1472; Blanksma, Proc. K. Akad. Wetensch. Amsterdam, 1905, 8, 170; Rec. trav. chim. 1906, 25, 165); by heating 5:6-dinitro-*m*-xylene with alcoholic ammonia for 3 hours at 180° (Blanksma), or with methyl alcoholic ammonia for 14 hours at 160° (Ibbotson and Kenner, Chem. Soc. Trans. 1923, 123, 1260). Long red needles, m.p. 67°–68° (I. and K.), 69° (H.), or 76° (W.; N. and F.; B.; G. and S.).

Acetyl-derivative; yellowish needles, pale yellow octahedra or colourless needles, m.p. 171° (I. and K.), 172°–173° (H.; T.; W. and S.), or 180° (W.; B.).

5-Nitro-*m*-4-xylylcarbimide forms microscopic yellow needles, m.p. 71°–72° (Vittenet, Bull. Soc. chim. 1899, (3) 21, 586, 948, 952). 5-Nitro-*m*-4-xyldine on treatment with sodium nitrite and dilute sulphuric acid is converted into 1:3-nitromethyl-indazole (G. and S.), but when diazotised and the solution treated with concentrated potassium hydroxide, potassium-5-nitro-*m*-xyleneisodiazooxide, pale yellow leaflets, is formed. This is oxidised with difficulty by potassium ferricyanide to 5-nitro-*m*-4-xylylnitramine, long vitreous yellow needles, m.p. 90°–91°, and 5-nitro-*m*-xylene (Bamberger and von Goldberger, Ber. 1920, 53, 2321).

6-Nitro-*m*-4-xyldine; by hydrolysing 6-nitro-*m*-4-xyldine 5-sulphonic acid with boiling hydrochloric acid (Jungbahn, Ber. 1902, 35, 3747); by the partial reduction of 4:6-dinitro-*m*-xylene with alcoholic ammonium sulphide (Fittig, Ahrens and Mattheides, Ann. 1868, 147, 18; Morgan, Micklethwait and Couzens, Chem. Soc. Trans. 1906, 89, 1289; Morgan and Micklethwait, *ibid.* 1907, 91, 360; Blanksma, Rec. trav. chim. 1909, 28, 92); together with 2-nitro-*m*-4-xyldine by nitrating *m*-4-xyldine with nitric and sulphuric acids (Nölting and Collin, Ber. 1884, 17, 261; Pearman, Chem. Soc. Trans. 1921, 119, 717). Orange-red needles, m.p. 123° (M., M. and C.).

Acetyl-derivative; monoclinic plates (Errera and Maltese, Gazz. chim. ital. 1903, 33, ii. 277), m.p. 160° (B.), or m.p. 159°–160° (Pearman); *diacetyl-derivative*, anorthic elongated colourless plates, m.p. 115°, converted into the monoacetyl-derivative, m.p. 161°, by boiling with dilute alcohol (Ahrens, Ann. 1892, 271, 15; E. and M.); *benzoyl-derivative*, white silky needles, m.p. 200° (E. and M.); *benzenesulphonyl-derivative*, colourless prismatic crystals, m.p. 148.5°, converted by methylation into benzenesulphonylmethyl-6-nitro-*m*-4-xyldide, m.p. 185° (M., M. and C.); *toluene-p-sulphonyl-derivative*, m.p. 192° (M. and M.); 6-nitro-*m*-4-xylylcarbimide, b.p. 212°–214°/97 mm., m.p. about 0° (Vittenet); the dinitro-dixylylcarbimide forms microscopic needles, which sublime (V.).

2:5-Dinitro-*m*-4-xyldine; by nitrating aceto-*m*-4-xyldide with nitric acid and sulphuric acid and keeping the mixture for 6–8 hours (Klages, Ber. 1896, 29, 310), or by nitrating with nitric acid [D 152] (Blanksma, Rec. trav. chim. 1909, 28, 92), followed by hydrolysis. Colourless needles, m.p. 115°, which deflagrate when heated (K.).

Acetyl-derivative? colourless needles, m.p. 226° (K.), or 233° (B.).

2:6-Dinitro-*m*-4-xyldine; by reducing 2:4:6-trinitro-*m*-xylene with ammonium sulphide (Miolati and Lotti, Gazz. chim. ital. 1897, 27, i. 296; Ibbotson and Kenner, Chem. Soc. Trans. 1923, 123, 1260; cf. Maltese, Gazz. chim. ital. 1909, 39, i. 517). Orange-yellow needles or dark-red prisms, m.p. 145°, or amber-coloured elongated rectangular prisms, m.p. 193° (I. and K.); *acetyl-derivative*, transparent lozenge-shaped crystals, m.p. 176° (I. and K.); *benzoyl-derivative*, by benzoylating the amine, also by nitrating 2-nitro-4-benzoylamino-*m*-xylene. Shining lamellae, m.p. 244° (M.), or colourless prismatic needles, m.p. 212° (I. and K.). The products described by Maltese appear to be of doubtful orientation.

5:6-Dinitro-*m*-4-xylidine; by nitrating 5-nitro-aceto-*m*-4-xylidide at the ordinary temperature with nitric acid and sulphuric acid (Blanksma, *Rec. trav. chim.* 1906, 25, 165; *Proc. K. Akad. Wetensch. Amsterdam*, 1905, 8, 70), or by nitrating 6-nitro-aceto-*m*-4-xylidide with nitric acid (D 1.52), or with a mixture of nitric and sulphuric acids, followed by hydrolysis (Blanksma, *Rec. trav. chim.* 1909, 23, 92). Yellow crystals, m.p. 170°.

Acetyl-derivative; yellow crystals, m.p. 217°.

5-Bromo-6-nitro-*m*-4-xylidine; by brominating 6-nitro-*m*-4-xylidine (Nölting, Braun and Thesmar, *Ber.* 1901, 34, 2242). Large prisms, m.p. 66°–67°.

5-Nitromethyl-*m*-4-xylidine; by boiling the nitrosamine with aniline and hydrochloric acid in alcoholic solution for 14 hours (Pinnow and Oesterreich, *Ber.* 1898, 31, 2926). Long carmine-red plates with a green reflex, m.p. 58°.

Nitrosamine; by nitrating the xylylmethyl-nitrosamine with nitric acid (D 1.4) at low temperatures (P. and O.). Yellowish crystalline powder, m.p. 63°.

6-Nitro-4-methylamino-*m*-xylene; *toluene-*p*-sulphonyl-derivative*, colourless prismatic crystals, m.p. 135°–136°, obtained by treating toluene-*p*-sulphonyl-6-nitro-*m*-4-xylidine with methyl iodide and alcoholic soda (Morgan and Micklethwait); *benzene-sulphonyl derivative*, colourless prisms, m.p. 184°–185° (Morgan, Micklethwait and Couzens, *Chem. Soc. Trans.* 1906, 89, 1289).

6-Nitro-4-dimethylamino-*m*-xylene; by heating a mixture of the hydrobromide of 6-nitro-*m*-4-xylidine and methyl alcohol for 5 hours at 160° (Morgan and Micklethwait, *Chem. Soc. Trans.* 1907, 91, 360). It forms a picrate which melts with violent decomposition at 170°–173°.

***m*-4-Xylidine 6-sulphonic acid**; by heating *m*-xylene 4-sulphonamic acid at 220°–230° for a short time; in low yield together with the 6-sulphonic acid as main product by adding *m*-xylidine to boiling chlorosulphonic acid; by heating the acid sulphate of *m*-xylidine at 210°–230° for 2½–3 hours under reduced pressure, or heating the sulphate similarly with four times its weight of *m*-xylidine (Junghahn, *Ber.* 1902, 35, 3747); by heating *m*-xylidine sulphate at 160° and then at 220° while a current of carbon dioxide or air is passed through the mass (Junghahn, *Chem. Ind.* 1903, 26, 57); by heating *m*-4-xylidine with 1 mol. of 100 p.c. sulphuric acid at 185°–195° for 6 hours (Armstrong and Wilson, *Chem. Soc. Proc.* 1900, 17, 229). Anhydrous rhombic plates. The sulphonic group is removed when the acid is heated with concentrated hydrochloric acid for 1½ hours at 150°–155° (J.). KA', anhydrous white leaflets; NaA', leaflets; BaA', +2H₂O, quadratic tables; PbA', anhydrous white needles; AgA', anhydrous white needles (J.).

Potassium acetyl-*m*-4-xylidide 5-sulphonate; spindle-shaped needles, by acetylating potassium *m*-4-xylidine 5-sulphonate (A. and W.).

***m*-4-Xylidine 6-sulphonic acid**; by sulphonating aceto-*m*-4-xylidide at 140° with 1½ times its weight of 20 p.c. fuming sulphuric acid and boiling the solution after the addition of water (Moody, *Chem. Soc. Proc.* 1891, 7, 189); by sulphonating *m*-4-xylidine with slightly fuming sulphuric acid at 140°–150° (Jacobsen and Ledderboge, *Ber.* 1883, 16, 193; cf. Deume-

landt, *Zeit. für Chem.* 1866, 2, 22; Limpriht, *Ber.* 1885, 18, 2172); by reducing 4-nitro-*m*-xylene 6-sulphonic acid with ammonium sulphide (J. and L.); by the nitration and subsequent reduction of *m*-xylene 4-sulphonic acid, or by sulphonating *m*-4-xylidine (Nölting and Kohn, *Ber.* 1886, 19, 137); by heating symm.-di-*m*-xylyl carbamide with sulphuric acid (D 1.711) at 150°–160° (Cazeneuve and Moreau, *Bull. Soc. chim.* 1898, (3) 19, 21). Long flat needles. NaA' + H₂O, large transparent rhombic plates; KA', large transparent rhombic plates; BaA' + H₂O, aggregates of microscopic needles (J. and L.), or +2H₂O (Sartig, *Ann.* 1885, 230, 333; Nölting and Kohn). When treated with nitric acid the sulphonic acid does not yield a nitroamine but forms 2-nitro-4-diazo-*m*-xylene 6-sulphonic acid, needles, which explode on heating (Zincke and Maué, *Ann.* 1905, 339, 202).

Acetyl-derivative; by treating aceto-*m*-4-xylidide with 3 times its weight of fuming sulphuric acid and keeping at the ordinary temperature until dissolved (Junghahn, *Ber.* 1900, 33, 1364).

6-Nitro-*m*-4-xylidine 5-sulphonic acid; needles + 1½H₂O (Junghahn, *Ber.* 1902, 35, 3747). KA', glistening golden-yellow needles + H₂O, or pale yellow needles when anhydrous. The free acid yields 6-nitro-*m*-4-xylidine when boiled with hydrochloric acid.

5-(?)Bromo-*m*-4-xylidine 6-sulphonic acid; by brominating the sulphonic acid in alkaline solution, followed by acidification, or by the action of bromine or hydrobromic acid on a solution in glacial acetic acid. No dibromoderivative could be obtained, as attempted further bromination eliminated the sulphonic group (Nölting and Kohn, *Ber.* 1886, 19, 137).

Nitro-*m*-4-xylidine 6-sulphonic acid; by nitrating *m*-4-xylidine 6-sulphonic acid (Sartig, *Ann.* 1885, 230, 333; Limpriht, *Ber.* 1885, 18, 2172). KA' + 1½H₂O, large rhombic plates; BaA' + 1½H₂O, yellow rhombic plates; PbA' + H₂O, yellow glistening needles.

***m*-5-Xylidine, or *s*-*m*-xylidine**; by reducing 5-nitro-*m*-xylene (Wroblewski, *Ann.* 1881, 207, 95; Töhl, *Ber.* 1885, 18, 362; Nölting and Forel, *Ber.* 1885, 18, 2678; Noyes, *Amer. Chem. J.* 1888, 20, 789; Willgerodt and Schmierer, *Ber.* 1906, 38, 1472); from mesitylene and from *m*-4-xylidine (Haller, Adams and Wherry, *J. Amer. Chem. Soc.* 1920, 42, 840). Liquid, b.p. 220°–221°, D₂₀ 0.9035, or b.p. 220°/739 mm., D₂₀ 0.972 (N. and F.). B'HCl, long needles; B'HNO₃, long needles; B'H₂SO₄ + H₂O; B'H₂PO₄, needles (Raikow and Scharbanow, *Chem. Zeit.* 1901, 25, 244); B'H₂PO₄, crystals (R. and S.).

Formyl-derivative, prisms, m.p. 76.5° (Limpach, *Ber.* 1888, 21, 643). **Acetyl-derivative**; large flat needles, m.p. 144.5° (W.), or 138° (Töhl, *Ber.* 1885, 18, 362), or 140.5° (Nölting and Forel, *ibid.* 2678), or m.p. 139.6°–140.2°, n_D 1.45, n_F 1.69 (H., A. and W.).

***m*-5-Xylidine** when heated with methyl alcohol at 250°–300° yields isocumidine (Limpach; Nölting and Forel), and forms *m*-xyloquinone when oxidised (Nölting and Forel, *Bull. Soc. chim.* 1884, 42, 332).

4-Chloro-*m*-5-xylidine; together with a little dichloro-*m*-5-xylidine by reducing 4-chloro-5-nitro-*m*-xylene with tin and hydrochloric acid

Klages, Ber. 1896, 29, 310). Oil, b.p. 251°, solidifying on cooling. It combines with the carbon dioxide of the air, and forms a *benzoyl-derivative*, m.p. 218°.

Dichloro-m-5-xylidine (see above). Colourless needles, m.p. 72°, b.p. 265°–266°; *benzoyl-derivative*, m.p. 158° (K.).

2:4:6-Tribromo-*m-5-xylidine*; by brominating *m-5-xylidine* in glacial acetic acid solution (Jaeger and Blanksma, Rec. trav. chim. 1906, 25, 352; Proc. K. Akad. Wetensch. Amsterdam, 1905, 8, 153). Colourless prisms, m.p. 195°.

2-Nitro-*m-5-xylidine*; together with the 4-nitro-isomerido by nitrating a sulphuric acid solution of *m-5-xylidine* with nitric and sulphuric acids (Ibbotson and Kenner, Chem. Soc. Trans. 1923, 123, 1260). Orange rectangular prisms, m.p. 132°. *Acetyl-derivative*; prisms, m.p. 163°.

4-Nitro-*m-5-xylidine*; in small quantity by heating 4:5-dinitro-*m-xylene* with methyl alcoholic ammonia for 14 hours at 160° (Ibbotson and Kenner); by nitrating a solution of *m-5-xylidine* in sulphuric acid with a mixture of nitric and sulphuric acids (Nölting and Forel, Ber. 1885, 18, 2668; Ibbotson and Kenner). It melts at 56° (I. and K.), or 54° (N. and F.). *Acetyl-derivative*, m.p. 114° (I. and K.).

2:6-Dinitro-*m-5-xylidine*; by the action of alcoholic ammonia on 2:5:6-trinitro-*m-xylene* (Blanksma, Rec. trav. chim. 1906, 25, 165; Proc. K. Akad. Wetensch. Amsterdam, 1905, 8, 70). It melts at 94°.

4:6-Dinitro-*m-5-xylidine*; by partial reduction of 4:5:6-trinitro-*m-xylene* (Blanksma, Rec. trav. chim. 1909, 28, 92), or by the action of alcoholic ammonia on the corresponding trinitro-*xylene* at 110° (Blanksma, Rec. trav. chim. 1906, 25, 165; Proc. K. Akad. Wetensch. Amsterdam, 1905, 8, 70). Yellow crystals, m.p. 101°.

2:4:6-Trinitro-*m-5-xylidine*; by treating 2:4:6-trinitro-5-chloro-*m-xylene* with alcoholic ammonia at 130° (Klages and Knoevenagel, Ber. 1895, 28, 2044). Yellowish-brown needles, which sublime, m.p. 206°. *Phenylamino-derivative*, long yellow needles, m.p. 175° (K. and K.).

4-Chloro-2:6-dinitro-*m-5-xylidine*; by heating 4-chloro-2:5:6-trinitro-*m-xylene* with alcoholic ammonia for 2 hours on the water-bath (Blanksma). Yellow crystals, m.p. 186°.

2-Bromo-4:6-dinitro-*m-5-xylidine*; by the action of ammonia at 150° on 2:5-dibromo-4:6-dinitro-*m-xylene* (Blanksma); by the action of bromine on 4:6-dinitro-*m-5-xylidine* in glacial acetic acid solution (Blanksma). Yellow crystals, m.p. 183°.

4-Bromo-2:6-dinitro-*m-5-xylidine*; by brominating 2:6-dinitro-*m-5-xylidine* (Blanksma); by the action of alcoholic ammonia on 4-bromo-2:5:6-trinitro-*m-xylene* or 4:5-dibromo-2:6-dinitro-*m-xylene* (Blanksma). It melts at 186°.

Dimethyl-m-5-xylidine; liquid, b.p. 226.5°–227.5° (Nölting, Ber. 1891, 24, 563; cf. Limpach, Ber. 1888, 21, 643). The trimethylammonium iodide forms white needles (N.).

2-Nitroso-*derivative*, greenish-yellow needles or green prisms, m.p. 104° (Pechmann and Nold, Ber. 1896, 31, 557).

2:6-Dinitromethyl-*m-5-xylidine*; by the

action of methylamine on 2:5:6-trinitro-*m-xylene* (Blanksma, Rec. trav. chim. 1902, 21, 327; 1906, 25, 165; Proc. K. Akad. Wetensch. Amsterdam, 1905, 8, 70). Yellow crystals, m.p. 27°. When nitrated with nitric acid (D 1.52) it yields 2:4:6-trinitro-*m-xylidyl-5-methylnitramine*, m.p. 181° (B.).

4:6-Dinitromethyl-*m-5-xylidine*; by the action of methylamine on 4:5:6-trinitro-*m-xylene* (B.). Yellow crystals, m.p. 85°. When nitrated with nitric acid (D 1.52) it yields 2:4:6-trinitro-*m-xylidyl-5-methylnitramine*, m.p. 81° (B.).

2:4:6-Trinitromethyl-*m-5-xylidine*; by the action of methylamine on trinitro-*m-xylidylmethyl ether* (B.). Yellow crystals, m.p. 164°.

2:4:6-Trinitroethyl-*m-5-xylidine*, crystals, m.p. 122° (B.).

2-Bromo-4:6-dinitromethyl-*m-5-xylidine*; by brominating 4:6-dinitromethyl-*m-5-xylidine*, or by the action of methylamine at 170° on 2:5-dibromo-4:6-dinitro-*m-xylene* (B.). Long yellowish-red needles, m.p. 146°. When nitrated it yields 2-bromo-4:6-dinitro-*m-xylidyl-5-methylnitramine*, m.p. 103° (B.).

4-Bromo-2:6-dinitromethyl-*m-5-xylidine*; by the action of methylamine on 4-bromo-2:5:6-trinitro-*m-xylene* or 4:5-dibromo-2:6-dinitro-*m-xylene* (B.); by brominating 2:6-dinitromethyl-*m-5-xylidine* in glacial acetic acid (B.). It melts at 175°–176°, and on nitration yields the *nitramine*, m.p. 152° (B.).

2-Nitrosoethyl-*m-5-xylidine*; by ethylating *m-5-xylidine* with ethyl bromide, treating the product with nitrous acid, heating the nitrosoamine with alcoholic hydrochloric acid and basifying the yellow hydrochloride with ammonia (O. Fischer and Cammerloher, Ber. 1901, 34, 948). It forms steel-blue needles, m.p. 138°.

2:4-Diamino-*m-xylene*; by reducing 2:4-dinitro-*m-xylene* with tin and hydrochloric acid (Grevingk, Ber. 1884, 17, 2427; Nölting and Thesmar, Ber. 1902, 35, 628), or with iron and dilute hydrochloric acid (Morgan, Chem. Soc. Trans. 1902, 81, 86); by reducing β -dinitro-mesitylenic acid with tin and hydrochloric acid (Bamberger and Demuth, Ber. 1901, 34, 27). White needles, m.p. 65°–66° (N. and T.), or 64° (G.).

Di-formyl-derivative; colourless needles, m.p. 219°–220° (M.); *diacetyl-derivative*, felted needles, m.p. above 260° (M.); *dibenzoyl-derivative*, felted needles, m.p. 232° (M.), or m.p. 226°–5–227.5° (B. and D.).

6-Nitro-2:4-diamino-*m-xylene*; by reducing 4:6-dinitro-*m-2-xylidine* with ammonium sulphide (N. and T.). Long slender orange-coloured needles, m.p. 151°–152°.

2:5-Diamino-*m-xylene*; in a similar manner to the 2:4-diamino-*m-xylene* (N. and T.); by reducing 2-nitro-*m-5-xylidine* with stannous chloride (Ibbotson and Kenner, Chem. Soc. Trans. 1923, 123, 1260); by coupling *m-xylidine* with diazobenzene-*m-sulphonic acid* and reducing the product (N. and T.). Pearly plates, m.p. 103°–104° (N. and T.), or 101° (I. and K.).

Benzoyl-derivative; m.p. 234° (Klages, Ber. 1896, 29, 310).

4-Chloro-2:5-diamino-*m-xylene*; by reducing 4-chloro-2:5-dinitro-*m-xylene* with tin and

hydrochloric acid in alcoholic solution (Klages). Oil, volatile with steam, b.p. 280°–281°.

Benzoyl-derivative, m.p. 164°.

4 : 6-Dichloro-2 : 5-diamino-m-xylene; by reducing a suspension of 2 : 5-dinitro-4 : 6-dichloro-m-xylene in alcohol with stannous chloride (Claus and Runschke, J. pr. Chem. 1890, (2) 42, 110). White prisms or needles when pure, m.p. 176°. B'HCl, needles; B',H₂PtCl₆, yellowish-red scales, decomposing about 230°.

4 : 5-Diamino-m-xylene; by reducing 2 : 4-dibromo-5 : 6-dinitro-m-xylene with tin and hydrochloric acid (Jacobsen, Ber. 1888, 21, 2821); by reducing 5-nitro-m-4-xylydine with tin and hydrochloric acid (Hofmann, Ber. 1876, 9, 1292; N. and T.); by reducing aminoazo-m-xylene with tin and hydrochloric acid (Nölting and Forel, Ber. 1883, 18, 2683). Leaflets, flat needles, or rhombic plates, m.p. 77°–78° (N. and T.), m.p. 78·5° (J.), or m.p. 74°–75° (H.).

2 : 4-(or 4 : 5-) Diamino-m-xylene 6-sulphonic acid; by boiling 2-(or 5-) nitro-m-4-xylydine 6-sulphonic acid with a mixture of stannous chloride and hydrochloric acid (Sartig, Ann. 1885, 230, 333; Limpricht, Ber. 1885, 18, 2172). Prisms. The aqueous solution is coloured wine-red by ferric chloride. KA' + H₂O, slender prisms; BaA', + 3H₂O, microscopic tables; PbA₂, prisms; B'HCl + H₂O, prisms.

4-Methyl-4 : 5-diamino-m-xylene; by reducing 5-nitromethyl-m-4-xylydine with tin and hydrochloric acid (Pinnow and Oesterreich, Ber. 1898, 31, 2926). Oil, b.p. 260°–262°. B'HCl, m.p. 225°.

Nitrosoamine, white plates, m.p. 81°; picrate, light yellow prisms, m.p. 128°; acetyl-derivative, white plates, m.p. 135°; phenylthiocarbamide, prisms, m.p. 132°–132·5°.

4-Acetomethylamino-5-acetamino-m-xylene; needles, m.p. 195°–196° (P. and O.).

4 : 5-Dimethylamino-m-xylene; by reducing 1 : 3 : 4 : 6-tetramethylhydrobenzimidazole-2-ol with sodium and alcohol (O. Fischer and Römer, J. pr. Chem. 1906, (2) 73, 419). Oil, b.p. 245°–250°/730 mm. Dihydrochloride, white flat prisms.

4 : 6-Diamino-m-xylene; by reducing 4 : 6-dinitro-m-xylene with tin and hydrochloric acid (Luhmann, Ann. 1867, 144, 275; Fittig, Ahrens and Matthesides, Ann. 1868, 147, 15; Grevingk, Ber. 1884, 17, 2422), or with iron and dilute hydrochloric acid (Morgan, Chem. Soc. Trans. 1902, 81, 86); by reducing 6-nitro-m-4-xylydine (Witt, Ber. 1888, 21, 2418; Nölting and Thesmar, Ber. 1902, 35, 628); by reducing a dinitro-mesitylenic acid with tin and hydrochloric acid (Bamberger and Demuth, Ber. 1901, 34, 30). Long pale yellow needles, m.p. 104°–105° (N. and T.; M.), or 105°–105·5° (B. and D.).

Diformyl-derivative; flat silky needles, m.p. 182°–183° (M.); *diacetyl-derivative*, silky needles, m.p. above 260° (M.); *dibenzoyl-derivative*, small lustrous plates, m.p. 252°–253° (M.), or 258°–259° (corr.) (B. and D.); *4-acetyl-derivative*, needles, m.p. 164°–166° (Pearman, Chem. Soc. Trans. 1921, 119, 717); *4-benzene-sulphonyl-derivative*, colourless leaflets, m.p. 167° (Morgan, Micklethwait and Couzens, Chem. Soc. Trans. 1906, 89, 1289); *s-dibenzenesulphonyl-derivative*, prismatic needles, m.p. 176° (Morgan and Clayton, *ibid.* 1906, 89, 1054); *di-p-toluene-*

sulphonyl-derivative, small white needles, m.p. 221°–222° (Pearman).

Bromo-diamino-m-xylene; by the action of bromine water on diamino-m-xylene (Hofmann, Zeit. für Chem. 1865, 1, 555). Needles.

2-Nitro-4 : 6-diamino-m-xylene; together with a monoamine by treating 2 : 4 : 6-trinitro-m-xylene with alcoholic ammonium sulphide (Bussenius and Eisenstuck, Ann. 1860, 113, 159; Fittig and Velguth, Ann. 1868, 148, 6; Miolati and Lotti, Gazz. chim. ital. 1897, 27, i. 293). Long ruby-red prisms which sublime, m.p. 212°–213°.

4 : 6-Diamino-m-xylene 5-sulphonic acid; by reducing 6-nitro-m-4-xylydine 5-sulphonic acid with stannous chloride and hydrochloric acid. Long needles. KA', yellow pillars; BaA', + H₂O, quadratic tables (Junghahn, Ber. 1902, 35, 3747).

4-Methyl-4 : 6-diamino-m-xylene; by hydrolysing 4-toluene-p-sulphonyl-4-methyl-4 : 6-diaminoxylene hydrochloride with hydrochloric acid at 120°–130° in sealed tubes (Morgan and Micklethwait, Chem. Soc. Trans. 1907, 91, 360). Colourless plates from benzene, m.p. 57°, b.p. 166°–167°/10 mm.; very sensitive to oxidising agents.

Toluene-p-sulphonyl-derivative; by reducing toluene-p-sulphonyl-6-nitro-4-methylamino-m-xylene with iron and dilute acetic acid.

Hydrochloride, almost colourless prisms, m.p. 225°; *acetyl-derivative*, colourless felted needles, m.p. 176° (M. and M.); *benzene-sulphonyl-derivative*, oil; *hydrochloride*, leaflets, m.p. about 160° (Morgan, Micklethwait and Couzens.).

4-Dimethyl-4 : 6-diamino-m-xylene; by reducing 4-dimethylamino-6-nitro-m-xylene with tin and hydrochloric acid (M. and M.). Colourless oil, b.p. 149°–150°/21 mm., which is coloured red by exposure to air.

Benzoyl-derivative; colourless glistening plates, m.p. 123°; *benzene-sulphonyl-derivative*, colourless needles, m.p. 112°–113° (M. and M.).

s-Dimethyl-4 : 6-diamino-m-xylene; by hydrolysing 5-dibenzene-sulphonyldimethyl-4 : 6-diamino-m-xylene with concentrated hydrochloric acid in a sealed tube at 160° for 5 hours. Colourless plates, m.p. 100°–101° (Morgan and Clayton, Chem. Soc. Trans. 1906, 89, 1054).

Dinitrosoamine; pale yellow rectangular plates, m.p. 76°–77°; *s-dibenzene-sulphonyl-derivative*; by boiling *s-dibenzene-sulphonyl-4 : 6-diamino-m-xylene* with alcoholic sodium hydroxide and methyl iodide for 6 hours (M. and C.). Colourless crystals, m.p. 196°–197°.

Trimethyl-4 : 6-diamino-m-xylene; by hydrolysing benzene-sulphonyl-trimethyl-4 : 6-diamino-m-xylene with hydrochloric acid in a sealed tube at 130°–150° for 4 hours (M. and M.). Colourless crystals, m.p. 40°–42°, b.p. 145°/15 mm.

Benzene-sulphonyl-derivative; by heating benzene-sulphonyl-4-dimethyl-4 : 6-diamino-m-xylene with methyl iodide and alcoholic potassium hydroxide for 9 hours under a reflux (M. and M.). Lustrous colourless needles, m.p. 122°–123°.

Mononitrosoamine; almost colourless crystals, m.p. 45° (M. and M.).

4 : 6-Tetramethyldiamino-m-xylene; by heating 4 : 6-diamino-m-xylene hydrochloride or hydrobromide with excess of methyl alcohol in

a sealed tube at 180° (Morgan, Chem. Soc. Trans. 1902, 81, 650). Pale brownish-yellow oil, b.p. 124°–125°/12 mm.; D_{15}^{20} 0.9434. $B'H_2PtCl_6$, orange-yellow acicular prisms, m.p. above 200°.

Picrate; transparent yellow rhombic prisms, m.p. 193°–195°, or 202°–203°, according to the rate of heating.

p-Xylidine, *p-2-xylidine*, or *2-amino-1:4-xylene*; from commercial xylidine (Nölting, Witt and Forel, Bull. Soc. Ind. Mulhouse, 1888, 58, 630; Ber. 1885, 18, 2664; Witt, D. R. P. 34854 of 1885; Limpach, Eng. Pat. 11822 of 1886; Fr. Pat. 178616; D. R. P. 39947 of 1886; Hodgkinson and Limpach, Chem. Soc. Trans. 1900, 77, 65; Bayer and Co., D. R. P. 71969 of 1893; Schultz and Peteny, J. pr. Chem. 1907, 76, 331; Bornstein and Kleemann, D. R. P. 56322 of 1890); by reducing 2-nitro-*p*-xylene with iron and acetic acid (Schaumann, Ber. 1878, 11, 1537); together with methyl-*p*-xylidine by reducing di-1:4:2-xylene-methylenedihydroxylamine with aluminium amalgam in ethereal solution (Bamberger and Destraz, Ber. 1902, 35, 1874; see also Wroblewsky, Ann. 1881, 207, 91; Ber. 1879, 12, 1226; Jacobsen, Ber. 1884, 17, 159). Colourless liquid, b.p. 213°–5°/762 mm., which on prolonged cooling crystallises in large colourless tablets, m.p. 15°–5° (Michael, Ber. 1893, 26, 39); b.p. 215°/739 mm.; D_{15}^{20} 0.981 (N., W. and F.). or b.p. 217°–1° (U.). $B'HCl$, m.p. 228°, b.p. 245°–4°/728 mm., or b.p. 247°–4°/760 mm (Ullman, Ber. 1898, 31, 1699); $B'HCl + xH_2O$, plates (S.); $B'HNO_3$, plates or flat needles (N., W. and F.); $B'HNO_3$, plates or needles (N., W. and F.; S.); $B'_2H_2SO_4$, small plates (N., W. and F.); $B'_2H_2C_2O_4$, pink prisms, converted on heating to 125°–130° into oxal-*p*-xylidide, slender colourless needles, which sublime at 125° without melting (S.); *telluribromide*, small brownish-red laths (Gutbier, Flury and Ewald, J. pr. Chem. 1912, (2) 86, 150); $B'_2H_2PO_4$, needles (Rackow and Scharbanow, Chem. Zeit. 1901, 25, 244).

Formyl-derivative; long colourless needles, m.p. 111°–112°, coloured red on keeping (Pfug, Ann. 1889, 255, 168), or m.p. 116°–117° (Hodgkinson and Limpach); *acetyl-derivative*, glistening needles, m.p. 139° (N., W. and F.; Schaumann); *benzoyl-derivative*, needles, m.p. 140° (P.); *benzylidene-derivative*, yellowish plates, m.p. 102°–103° (Bayer & Co., D. R. P. 71969 of 1893), or 101°–102° (P.); *benzyl-derivative*, light yellow oil, b.p. 320°–325° (*hydrochloride*, colourless needles) (P.); *m-nitrobenzylidene-derivative*, yellow needles, m.p. 126° (P.); *p-nitroso-derivative*, green needles, m.p. 169° (P.); *p-xyllyphthalamide*, silky needles, m.p. 209°–210°, *s-p-xyllyphthalimide*, slender needles, m.p. 147°–148°, and *as-p-xyllyphthalimide*, amber needles, m.p. 178°–181°, are obtained by the action of phthaloylchloride on *p*-xylidine in ethereal solution at low temperatures (Kuhara and Komatsu, Mem. Coll. Sci. Eng. Kyōto, 1910, 2, 365). When *p*-xylidine is heated with finely powdered arsenic acid and the product is distilled, 4-amino-2:5-xyllyphthalic acid, m.p. 215° (when anhydrous), is formed. The therapeutic germicidal action of this compound is analogous to that of *p*-amino phenylarsenic acid (M. L. B., Eng. Pat. 14937 of

908; U.S. Pat. 913940; D. R. P. 219210 of 1907). When *p*-xylidine is condensed with benzaldehyde in presence of alcoholic hydrochloric acid, phenyl-di-*p*-amino-di-*p*-xylidimethane, m.p. 208°, is formed (Schultz and Peteny, J. pr. Chem. 1907, (2) 76, 331). *p*-Xylidine can be converted by the Sandmeyer reaction into *p*-xylene-2-nitrile, yellow oil, b.p. 223°–226°/730 mm., slowly volatile with steam (Schmid, Decker and Hock, Ber. 1906, 39, 933). By heating *p*-xylidine with sulphur at 200° a thio-base, $C_{10}H_{12}N_2S$, long yellowish needles, m.p. 144°, is formed (Anschtütz and Schultz, Ber. 1889, 22, 580).

5-Chloro-p-2-xylidine; together with *p*-xylidine by reducing nitro-*p*-xylene with tin and hydrochloric acid (Jannasch, Ann. 1875, 176, 177; Kluge, Ber. 1885, 18, 2098); by heating di-*p*-xylidyl-O-methylenedihydroxylamine with hydrochloric acid (Bamberger and Baum, Ber. 1900, 33, 941). Plates, m.p. 91° (B. and B.), or 92°–93° (J.; K.); $B'HCl + 2H_2O$, long needles (J.); $B'HNO_3$, large rhombohedral tables (J.); $B'_2H_2SO_4 + 2H_2O$, small needles (J.); $B'_2H_2C_2O_4$, rhombic tables (J.).

Acetyl-derivative; colourless needles, m.p. 171° (J.; K.).

Bromo-p-2-xylidine; by brominating formyl-*p*-xylidine in glacial acetic acid solution, followed by hydrolysis with alcohol and hydrochloric acid (D 1:19) for 6 hours under a reflux (E. Fischer and Windaus, Ber. 1900, 33, 1975). Needles, m.p. 96° (corr.). *Acetyl-derivative*, large prisms, m.p. 148° (150° corr.).

5-Bromo-p-2-xylidine; by reducing 2-bromo-5-nitro-*p*-xylene with iron powder and sulphuric acid (Blanksma, Chem. Weekblad, 1913, 10, 136). Colourless crystals, m.p. 96°.

Acetyl-derivative; from the bromo-xylidine, or by brominating aceto-*p-2*-xylidide in glacial acetic acid solution (B.). Colourless crystals, m.p. 180°.

3:5-Dibromo-p-2-xylidine, by brominating *p*-xylidine or *p-2*-xylidine 5-sulphonic acid (Nölting and Kohn, Ber. 1886, 19, 137; Blanksma, l.c.; Jaeger and Blanksma, Rec. trav. chim. 1906, 25, 352; Proc. K. Akad. Wetensch. Amsterdam, 1905, 8, 153). Needles, m.p. 65° (N. and K.; B.).

Acetyl-derivative; colourless crystals, m.p. 192°.

3:6-Dibromo-p-2-xylidine; by reducing 2:5-dibromo-3-nitro-*p*-xylene with iron powder and acetic acid (Auwers and Baum, Ber. 1896, 29, 2344). Needles, m.p. 91°–92°.

5-Nitro-p-2-xylidine; by nitrating *p*-xylidine with nitric acid and an excess of sulphuric acid (Nölting, Witt and Forel, Ber. 1885, 18, 2667); by reducing 2:5-dinitro-*p*-xylene with alcoholic ammonium sulphide (Kostanecki, Ber. 1886, 19, 2318; Blanksma, Chem. Weekblad, 1913, 10, 136). It melts at 142° (B.).

Acetyl-derivative; long needles, m.p. 166° (N., W. and F.). A *nitroacetyl-p-xylidide*, slightly yellow irregular crystals, m.p. 192°, is obtained by nitrating aceto-*p-2*-xylidide (Schaumann, Ber. 1878, 11, 1537).

6-Nitro-p-2-xylidine; by reducing 2:6-dinitro-*p*-xylene with hydrogen sulphide in ammoniacal solution (Fittig, Ahrens and Mattheides, Ann. 1868, 147, 22; Kostanecki). Long yellow needles, m.p. 96°. $B'HCl$, long needles,

Acetyl-derivative; small needles, m.p. 180° (K.).

3:5-Dinitro-*p*-2-*xylylidine*; by prolonged boiling of 2:3:5-trinitro-*p*-xylene with alcoholic ammonia (Nölting and Geissmann, Ber. 1886, 19, 144). Yellow needles, m.p. 202°–203°.

3:5-Dinitro-*p*-*xylyl*-2-nitramine; by adding *p*-xylylidine sulphonic acid to nitric acid at –5° (Zincke and Ellenberger, Ann. 1905, 339, 202). Colourless needles, m.p. 130° (decomp.). When boiled with phenol it yields 3:5-dinitro-*p*-2-*xylylidine*.

3-Bromo-5-nitro-*p*-2-*xylylidine*; by brominating 5-nitro-*p*-2-*xylylidine* in glacial acetic acid solution (Blanksma, Chem. Weekblad, 1913, 10, 136). Pale yellow crystals, m.p. 125°.

Acetyl-derivative; colourless crystals, m.p. 208°.

3:5-Dibromo-6-nitro-*p*-2-*xylylidine*; by brominating 6-nitro-*p*-2-*xylylidine* (B.); by hydrolysing the acetyl-compound obtained by nitrating 3:5-dibromo-aceto-*p*-2-*xylylidine* (B.). Yellow crystals, m.p. 176°.

Acetyl-derivative; colourless crystals, m.p. 256°.

p-2-*Xylylidine* 5-sulphonic acid; by heating *p*-2-*xylylidine* sulphate at 160°, then at 220°, and at the same time passing a current of carbon dioxide or air through the mass (Junghahn, Chem. Ind. 26, 57); by sulphonating *p*-*xylylidine* at 230° for 5–6 hours with sulphuric acid (D 184) (Nölting, Witt and Forel, Ber. 1885, 18, 2664; Bull. Soc. Ind. Mulhouse, 1888, 58, 630; Nölting and Kohn, Ber. 1886, 19, 137). It forms prismatic plates or needles, which begin to char at 230° but do not melt at 300° (Carslake and Huston, J. Amer. Chem. Soc. 1914, 36, 1244). NaA', pearly plates; BaA', +7H₂O, leaflets. This acid on treatment with bromine yields 3:5-dibromo-*p*-2-*xylylidine*. The dry distillation of sodium *p*-2-*xylylidine* 5-sulphonate yields *p*-*xylylidine*, whilst on oxidation with chromic acid *p*-xyloquinone is obtained (N. and K.).

Acetyl-derivative; by heating aceto-*p*-2-*xylylidine* for a long time with fuming sulphuric acid (20 p.c. SO₃) at a temperature which does not exceed 40° (Junghahn, Ber. 1900, 33, 1364). Long greyish-white needles +2H₂O.

Acetyl-sulphonyl-derivative; by the action of chlorosulphonic acid on aceto *p*-*xylylidine* at 80° for one hour. Colourless needles, m.p. 160°; *sulphonanilide*, m.p. 213°–214°. On treatment with zinc dust in acetic-hydrochloric acid solution the acetyl sulphonyl-derivative is converted into 2:2'-diacetyl-*p*-*xylyl* 5:5'-disulphide, long needles, m.p. 284°–285° (Johnson and Smiles, Chem. Soc. Trans. 1923, 123, 2384).

Aceto-*p*-2-*xylylidine* 5-sulphinic acid; by reducing the acetyl-sulphonyl-derivative of *p*-2-*xylylidine* 6-sulphonic acid with aqueous sodium sulphite. Colourless needles, m.p. about 125° (decomp.) (Johnson and Smiles).

p-2-*Xylylidine* 6-sulphonic acid (see also Caze-neuve and Moreau, Bull. Soc. chim. 1898, (3) 19, 24); together with the above 5-sulphonic acid by the successive nitration and reduction of *p*-xylene sulphonic acid with ammonium sulphide (Nölting and Kohn, l.c.; Bull. Soc. Ind. Mulhouse, 1888, 58, 636). It crystallises in needles and yields a monobromo-derivative when treated with bromine. It is not oxidised to *p*-xyloquinone by chromic acid.

BaA', +7H₂O (Carslake and Huston).

3-(or 5-)Bromo-*p*-2-*xylylidine* 6-sulphonic acid; by brominating *p*-2-*xylylidine* 6-sulphonic acid (N. and K.). Small white leaflets, KA'. With excess of bromine a substance, yellow needles, m.p. 106°–107°, which appears to be a brominated quinone, is obtained.

Methyl-p-2-*xylylidine*; together with *p*-2-*xylylidine* by reducing di-1:4:2-xylenemethyl-enedihydroxylamine with aluminium amalgam in ethereal solution (Bamberger and Destraz, Ber. 1902, 35, 1874); by boiling formyl-*p*-2-*xylylidine* with potassium hydroxide and methyl iodide in methyl alcoholic solution and treating the product with concentrated hydrochloric acid (Pflug, Ann. 1889, 255, 168). Yellowish oil, b.p. 225°–227°/735 mm.; D 0.962.

Nitrosoamine; yellow oil.

p-Nitroso-derivative; green needles with a blue reflex, m.p. 164° (P.; B. and D.).

3:5-Dinitromethyl-*p*-2-*xylylidine*; by heating 2:3:5-trinitro-*p*-xylene with methylamine in a sealed tube in alcoholic solution (Blanksma, Rec. trav. chim. 1905, 24, 46). Slender orange crystals, m.p. 175°. On nitration it yields a nitroamine, m.p. 94°.

3:5-Dinitroethyl-*p*-2-*xylylidine* (Blanksma). It melts at 133°, and on nitration yields a nitroamine, m.p. 36°.

Dimethyl-p-2-*xylylidine*; by heating *p*-*xylylidine* with dimethyl sulphate for 1 hour at 145°. Oil, b.p. 205° (Bielecki and Koleniew, Anzeiger Akad. Wiss. Krakau, 1908, 296); *methiodide*, prisms, m.p. 219°–222° (corr.), or 215°–218° (uncorr.) (E. Fischer and Windaus, Ber. 1900, 33, 345).

5-Bromodimethyl-*p*-2-*xylylidine* *methiodide*; leaflets, decomposing about 188° (uncorr.), or 191° (corr.) (E. Fischer and Windaus, *ibid.* 1970).

Some *xylylidine* derivatives of doubtful orientation have been described by Genz (Ber. 1869, 2, 686; 1870, 3, 225); Hübner (Ann. 1881, 208, 321); Lippmann and Strecker (Ber. 1879, 12, 82); Bussenius and Eisenstuck (Ann. 1860, 113, 165; cf. Ann. 1865, 133, 45; 1867, 144, 277; 1868, 147, 24); Krell (Ber. 1872, 5, 879); Hofmann (Ber. 1872, 5, 712); Seemann (Ber. 1873, 6, 446); Girard and Vogt (Bull. Soc. chim. 1872, (2) 18, 69); Wallach (Ann. 1874, 173, 283).

2:3-Diamino-*p*-xylene; by reducing the corresponding dinitro-*p*-xylene or nitro-*p*-*xylylidine* (Lellmann, Ann. 1885, 228, 251; Nölting and Geissmann, Ber. 1886, 19, 145; Nölting and Thesmar, Ber. 1902, 35, 628). It sublimes in needles, m.p. 75°. It gives a cherry-red coloration with ferric chloride, and with sodium nitrite in acetic acid solution a yellow solution and then a white precipitate is formed. The hydrochloride is coloured a deep red by ferric chloride.

2:5-Diamino-*p*-xylene; by reducing xylene-azoxylidine with tin and hydrochloric acid (Nietzki, Ber. 1880, 13, 470; Nölting and Forel, Ber. 1885, 18, 2685); by reducing 5-nitro-*p*-2-*xylylidine* (Nölting, Witt and Forel, Bull. Soc. Ind. Mulhouse, 1888, 58, 630; Ber. 1885, 18, 2666; Nölting and Thesmar, Ber. 1902, 35, 628; von Kostanecki, Ber. 1886, 19, 2318; Marchwald, Ber. 1890, 23, 1021); by reducing *p*-xyloquinone dioxime with tin and hydrochloric

acid (Sutkowski, Ber. 1887, 20, 979). Pale yellow or colourless needles, which sublime, m.p. 149°–150° (N. and T.; N.), or leaflets, m.p. 142° (decomp.) (S.). It yields xyloquinone, m.p. 123°, on oxidation. $B''2HCl$, leaflets; $B'H_2SO_4$, crystalline mass.

2:6-Diamino-p-xylene; by reducing 6-nitro-*p*-2-xylydine sulphonic acid with tin and hydrochloric acid (Blanksma, Rec. trav. chim. 1905, (2) 24, 320); by reducing the corresponding dinitro-compound (Lellmann, Ann. 1885, 228, 252; Nölting and Geissmann, Ber. 1886, 19, 145; Nölting and Thesmar, Ber. 1902, 35, 628). It sublimes in needles, m.p. 101.5°–102.5° (L.; N. and G.), or long yellowish prisms, m.p. 102°–103° (N. and T.). No coloration is produced by ferric chloride or potassium dichromate in neutral solution, but in warm sulphuric acid solution these oxidising agents produce a cherry-red coloration and a quinone odour.

5-Nitro-2:3-diamino-p-xylene; by reducing 3:5-dinitro-*p*-xylyl-2-azoimidé with alcoholic sodium sulphide (Fries and Noll, Ann. 1912, 389, 305). Red needles, m.p. 169°. When boiled with formic acid it yields 6-nitro-4:7-dimethylbenziminazole, m.p. 221°, and with sodium nitrite and hydrochloric acid in boiling alcoholic solution 5-nitro-4:7-dimethyl-1:2:3-benzotriazole, m.p. above 300°, is formed (F. and N.).

2-Methyl-2:5-diamino-p-xylene; by reducing 5-nitroso-*p*-2-methylxylydine with tin and hydrochloric acid (Pflug, Ann. 1889, 255, 168). Almost colourless needles, m.p. 83°.

F. M. R. and J. S. H. D.

XYLOSE v. CARBOHYDRATES. Ling and Nanji have slightly modified Hudson and Hardinge's method of extraction from maize cobs, whereby the yields of xylose have the correct specific rotatory power and melting-point, the yield was uniformly 10–12 p.c. of the cobs used (Chem. Soc. Trans. 1923, 123, 620).

Y

“Y” ALLOY. An alloy consisting of 4 p.c. copper, 2 p.c. nickel, 1.5 p.c. magnesium, and the rest aluminium. Has a tensile strength of about 20 tons per sq. in. and an elongation of 5–6 p.c. after suitable heat treatment. Rods of this alloy will stand 12,000,000 reversals of a maximum fibre stress of 7 tons per sq. in. The most satisfactory heat treatment of the cast rods consists in plunging them into a salt bath at $520 \pm 5^\circ$, maintaining them at the same temperature for 6 hours, then quenching them in boiling water. Temperatures above 525° cause the formation of blisters on the surface of the rods, but if these are turned off the rods have a satisfactory tensile strength (Rosenhain, Archbutt and Wells, Inst. Metals, March 1923; J. Soc. Chem. Ind. 1923, 358 A.).

YARA-YARA (*Nerolin*). Trade name for β -naphthyl methyl ester.

YATREN (*Griserin novum*). Trade name for iodo-hydroxyquinoline sulphonic acid, mixed with acid sodium carbonate.

YEAST v. FERMENTATION.

Yeast incubated in oxygenated water shows a diminished carbohydrate content and an increase in fat. Propyl, butyl, and isoamyl alcohols inhibit this conversion, whilst the sodium salts of formic, propionic, and butyric acids, glycol, glycerol, and acetone, in 0.1 M-solution, behave like water. Incubation in 0.5 p.c. solutions of ethyl alcohol, or of the sodium salts of acetic, lactic, and pyruvic acids gives the same results as 0.5 p.p. solutions of dextrose; in the first two cases increase of the total carbohydrate of the yeast-cell is observed. In the presence of dextrose, laevulose, and sucrose the yeast-cell stores both carbohydrate and fat. Maltose is exceptional in producing a greater carbohydrate and lesser fat storage than the other sugars investigated. It is suggested that maltose is assimilated as such by the yeast-cell. Continuous oxygenation during incubation greatly increases the amount of fat produced, but has little or no effect on the carbohydrate. In oxygenated solutions, added phosphate reduces the amount of carbohydrate stored and increases

the fat formation. Phosphate is taken up by the cell in proportion to the sugar concentration of the solution; more phosphate is taken up from oxygenated than from non-oxygenated solutions. It is suggested that the formation of hexose phosphate is the first stage in the conversion of carbohydrate into fat (I. S. MacLean and D. Hoffer, Bio-Chem. J. 1923, 17, 220; Chem. Soc. Abstr. 1924, 126, i. 352).

Influence of Nitrates on Yeast.—According to Fernbach and Nicolau (Ann. Brass. Dist. 22, 305, 321) fermentation experiments were carried out in nutrient solutions containing sucrose and mineral salts. Flasks containing the solution with increasing quantities of potassium nitrate were seeded with yeast from a mineral nutrient solution in quantities close to the limiting concentration (A. J. Brown), in order to suppress any complications arising from the multiplication of the yeast. After several days 'forcing' the alcohol was determined. A favourable effect was observed with additions of 5 and 10 grms. KNO_3 per litre both when the nitrogen in the nutrient solution was in the form of ammonium salts and when present only as nitrates. In the former case the effect was more marked at the beginning of fermentation, in the second the effect was more marked and persisted to the end of fermentation. It is concluded that the presence of potassium nitrate as the only source of nitrogen permits the yeast to carry through the fermentation completely. The value of nitric nitrogen cannot, however, be compared with that of nitrogen in other forms. Determination of the alcohol formed after $\frac{1}{3}$ of the sugar originally present had been fermented showed that the presence of nitrate does not modify the physiological properties of yeast from the point of view of alcohol formation. The nitrate acts simply as an accelerator to the zymase. Potassium nitrate appears to have no sensible effect on the other enzymes of yeast, though quantities greater than 40 p.c. have a retarding effect on the proteolytic enzymes. The authors confirm Fernbach and Lanzenberg's experiments, show-

ing that potassium nitrate has a harmful effect on the multiplication of yeast, and they further show that yeast is incapable of building up its cells from nitric nitrogen (*J. Soc. Chem. Ind.* 1924, 43, B. 610).

For the action of ultra-violet rays on yeast, see Fernbach (*Ann. Brass. et Dist.* 1923, 22, 97-100), who has discussed the results of the work of Romolo and Remi de Fazi. The mechanism of the ultra-violet rays is comparable to the effect of antiseptics. Industrial yeast is a mixture of cells of different ages and resisting powers. The rays destroy the weaker cells and activate the vigorous. The rays are not to be considered a means of revivifying all degenerate yeast, for the vitality of even the strongest cells of such a yeast is lowered, and as such is very sensitive to attack by the rays and an undesirable result is produced. This explains the unfavourable results obtained by several experimenters (*cf.* also H. Lüers and H. Christoph (*Zentr. Bakt. u. Parasit.* 1923, ii, 59, 8-13)).

For an account of the varieties of yeast from Saxi, see Takahashi, Yukawa, Eda, Yamamoto (*J. of the College of Agric. Imp. Univ. of Tokyo*, 1922, 7, 2).

For the dietary properties of yeast, see Nelson, Heller, and Fulmer (*J. Biol. Chem.* 1923, 57, 415-424).

Fermentation of Dextrose by Dried Yeast.—The rate of fermentation of dextrose by yeast dried by various methods has been measured by determining the rate of production of carbon dioxide. With such dried yeasts there usually occurs a more or less marked period of induction. Increase of the concentration of the yeast decreases this period. If the yeast is first of all incubated with sugar solution the induction period disappears. After being ground up in a mortar, dried yeast ferments sugar more slowly. Determination of the sugar at intervals during the fermentation by dried yeast shows that a certain disappearance of the carbohydrate takes place, amounting to from 20-50 p.c. of the sugar used, which cannot be accounted for by the carbon dioxide produced (*H. Sobotka, Zeitsch. physiol. Chem.* 1924, 134, 1-21; 1925, 145, 91; *Chem. Soc. Abstr.* 1924, i, 802; 1925, i, 865).

Effect of Nitrogenous Nutrition on the Activity of Brewer's Yeast.—Fermentation with brewer's yeast is most active and produces the maximum amount of ethyl alcohol and acid at 15° in a bouillon containing 0.1 p.c. of ammonium hydrogen carbonate (*I. Bay, Compt. rend. Soc. Biol.* 1923, 89, 1044-1045; *Chem. Zentr.* 1924, i, 680; *Chem. Soc. Abstr.* 1924, i, 802-803).

Role of the Reaction of the Medium in Selective Fermentation.—The fermentation of sugar solutions by 8 types of yeast has been studied, and in each case it has been found that levulose is at first attacked more readily than dextrose, until a point is reached, varying with the yeast employed and not occurring in the case of Sauternes yeast, at which the relative rate of attack is reversed. It was found possible to modify the course of the fermentation in other cases than that of the Sauternes yeast by decreasing the acidity of the solution (*Fernbach and Schiller, Compt. rend.* 1924, 178, 2196; *Chem. Soc. Abstr.* 1924, 126, i. 917).

Influence of Alkaloids of the Atropine, Cocaine, and Morphine Groups on Yeast Invertase.

—According to P. Rona, C. van Eweyk, and M. Tennenbaum (*Biochem. Zeitsch.* 1924, 144, 490), a series of alkaloids of the above groups have been found to possess an inhibiting influence on the action of yeast invertase. Although the intensity of the inhibition varies with the various alkaloids, the general inactivating influence proceeds logarithmically according to the concentration of the alkaloid present. The inhibition is reversible, and is influenced by the hydrogen-ion concentration of the medium. No connection exists between the optical configuration and the inhibitory power of *dl*-atropine and *l*-hyoscyamine; *l*-cocaine and *dl*-cocaine; and *l*-ecgonine and *d*-ecgonine. In none of these three cases was there any difference between the inhibitory power of the isomers. Tropine inhibits much less markedly than atropine, whilst tropic acid does not inhibit at all; nor does an equimolecular mixture of tropine and tropic acid have a greater inhibiting effect than tropine alone, *d*- and *l*-ecgonine do not inhibit, but, on the other hand, the chemically-related cocaine does. The substitution of the hydrogen of morphine by the methyl group (codeine) produced no apparent change in inhibitory power, but substitution by ethoxyl (dionine) produced a small though definite change (*Chem. Soc. Abstr.* 1924, 126, i. 468).

The effect of pyridine and nicotine respectively on the fermentative activity of yeast has been studied by M. Y. Otero (*Anal. Assoc. Quim. Argentina*, 1923, 11, 62), using 25 c.c. of a culture solution containing dextrose, to which 1 c.c. of yeast suspension and varying amounts of nicotine or pyridine were added. Increased activity was observed after the addition of as little as 0.05 mg. in the case of pyridine and 0.00005 mg. in the case of nicotine. No proportionality was observed between the change in activity and the amount of pyridine or nicotine added (*J. Soc. Chem. Ind.* 1923, 42, 1192 A).

Co-enzyme of Yeast.—The concentration, purification, and characterisation of co-enzyme are described by Euler and Myrbäck. A method has been devised for determining co-enzyme, based on the measurement of the carbon dioxide evolved with zymase and dextrose under standard conditions at $p_H = 6.2-6.6$. The fermentative power of dried yeast preparations is increased by the addition of co-enzyme and also by the addition of washed inactive yeast free from the co-enzyme. The rate of fermentation therefore depends on the relative quantities of zymase and co-enzyme, and it is assumed that the two together form a dissociable compound which constitutes the active enzyme. By the addition of either zymase or co-enzyme the dissociation of this active compound is suppressed, resulting in an increase in the activity of the mixture. The results on the thermostability of co-enzyme are similar to those arrived at by Tholin. Co-enzyme is decomposed rapidly in solutions more alkaline than $p_H 10$, shows maximum stability at $p_H 7$, and is still active in 0.5N hydrochloric acid ($p_H 0.6$). Contrary to the view hitherto accepted, it was found that lead acetate is capable of

precipitating the co-enzyme to a greater or less extent, according to the p_H of the solution. The co-enzyme is not affected by hydrogen sulphide, but is inactivated by traces of lead. When lead acetate was added to yeast juice containing the co-enzyme at p_H 6, the free phosphate and the hexosephosphate were precipitated and the co-enzyme was found mainly in the filtrate. When the latter was brought to p_H 8.3–10.0 the co-enzyme was almost completely precipitated. It could be recovered from the lead precipitate by suitable means, and such fractional precipitation may be employed for purification. It can also be purified in a solution free from phosphate, by adsorption on alumina, which is almost quantitative at p_H 10, whilst in acid solutions no adsorption occurs. The alumine adsorbate is strongly active and the co-enzyme is not eluted therefrom by water or very dilute acids, although it can be readily eluted quantitatively with 1 p.c. phosphate solution at p_H 6.3 (H. von Euler and K. Myrbäck, *Zeitsch. physiol. Chem.* 1924, 136, 107; *Chem. Soc. Abstr.* 1924, 126, i. 918).

YEAST FAT. Pressed yeast when treated with alcohol, light petroleum, or ether yields, on evaporation of the solvent, a brown liquid from which crystals of a sterol separate on standing, and from which lipins are precipitated by acetone. The crude yeast fat has a high but variable iodine value, ranging from 121 to 175.5, dependent chiefly on the amount of sterol present. The saponification value is low and shows wide variation from the same cause (138–199). The unsaponifiable matter present ranges from 25 to 45 p.c. According to I. S. MacLean and E. M. Thomas (*Bio-chem. J.* 14, 1920, 483, which contains a full bibliography), the fat contains palmitic, lauric, oleic, and linoleic acids, and an acid having the melting-point of arachidic acid. The pentadecic acid of Hinsberg and Roos (*Zeitsch. physiol. Chem.* 38, 1; 42, 189) is a mixture of palmitic and lauric acids, and their dodecenoic acid is possibly a mixture of lauric with oleic and linoleic acids.

The sterol present in yeast appears to be identical with the ergosterol isolated from ergot by Tanret. It exists partly in the free state and partly as fatty acid esters, and may constitute 20 p.c. of the total yeast fat. It is probably identical with the mycosterol isolated by Ikeguchi (*J. Biol. Chem.* 40, 1919, 175) from certain fungi, and is characteristic of the group of the cryptogams, as cholesterol is of the animal and phytosterol of the higher plant kingdom.

YEAST GUM v. GUMS.

YEAST JUICE, which has been boiled for 8 hours and so freed from co-enzyme, has a marked effect in increasing the activity of zymase in various yeasts. This effect is not due to a buffering action. It is ascribed to a 'zymase protector' (correlated with Euler's vitamin biocatalyst B. II.) which is also shown to have an anti-proteolytic action running parallel with the zymase-activating properties. It is suggested that the latter is due to protection of the enzyme—probably of a protein nature—from the proteolytic action of the endo-tryptase present in the yeast. This 'protective juice' also contains an activator for the zymase co-enzyme, and shows an anti-lipolytic

action again running parallel to the activating properties, and suggesting direct correlation or identity of the substances concerned. It was found that 'post war' yeasts grown in worts containing a high percentage of rice or maize show a lessened stability to maceration processes as compared with 'pre-war' yeasts (H. Haehn and H. Schifferdecker, *Biochem. Zeitsch.* 1923, 138, 209–268; *J. Soc. Chem. Ind.* 1923, 42, 850 A.).

YEAST, PRESSED OR BAKER'S. *Physical character.*—Pressed yeast, formerly called 'German' yeast, reaches the baker in the form of a very stiff creamy paste, which, on drying, readily crumbles to a coarse powder.

It should possess a bright creamy colour, an odour resembling that of sweet apples, a sharp, bitter but not unpleasant taste, and should not be sticky to the touch. Microscopically examined it should consist only of healthy oval or round cells, many of which should be budding. Chains of upwards of eight or even ten cells are not uncommonly seen. There should be no 'foreign' type of organism present, such as rods, sarcina forms, or moulds. A good sample of yeast will also be free from dead or disintegrating cells.

Pressed yeast after being kept for 5 to 10 days (depending on the weather) commences to deteriorate by drying and cracking into small pieces, which become exceedingly hard and develop a bad odour. The autodigestion and liquefaction of brewery yeast is not observed in distiller's pressed yeast.

Treatment of Yeast for Preservation of Vitality.—According to the Distillers' Company, Ltd., Edinburgh, and E. A. Meyer, Bristol (Eng. Pat. No. 204164, Sept. 27, 1923), pressed yeast is mixed with about one-sixth of its weight of cocoa butter or other fatty substance, which melts at a temperature sufficiently low to prevent damage to the yeast. The mixture is then dried at the ordinary or a slightly elevated temperature and the coating of fat around the cells is claimed to prevent deterioration of the yeast without further treatment (*J. Inst. Brewing Abstr.* 1924, 30, 243).

Before the war about 50 p.c. of the yeast used in the United Kingdom was imported from the Continent—mainly from Holland.

The several stages of the manufacture usually consist of:

- (i) Milling, steaming, malting or other preparation of the raw material;
- (ii) Admixture (mashing) of the raw or prepared material with water;
- (iii) Separation of the extracted raw material, leaving an aqueous extract technically called 'wash,' this extract being a nutrient liquid well suited to the vigorous reproduction of yeast;
- (iv) The admixture of seed yeast with the wash;
- (v) The collection of yeast from the fermented wash;
- (vi) The purification and pressing of the yeast.

In 1796 yeast was first pressed in bags with the aid of a press, much resembling the household linen press, whilst in 1860 iron-framed presses were first introduced. In 1878 a great discovery was made by Graham, who noticed

the increased rate of fermentation and benefit to the yeast of a gentle stream of air blown through the fermenting wash.

In Great Britain very little progress was made in the manufacture of yeast until after the repeal of the malt tax in 1880, whereby the distiller was enabled to make greatly advantageous changes in his method of mashing.

One of the first attempts to make a yeast specifically for baking purposes was made in the Midlands in 1888, when a process was used in which molasses were inverted by boiling with acid, the neutralised product being diluted and used as liquor to mash a mixture of malt-culms and bran. Drainage was effected through the usual false bottom; the unboiled wash diluted to about 1040°, and fermented by a bottom yeast. The outcrop was collected and pressed in small bags for distribution to the baker. This early process illustrates the general conduct of operations in a yeast distillery, the requirements being simple, namely, a liquid well suited to the rapid and healthy reproduction of the yeast organism. To push reproduction to its furthestmost limits without injury to the yeast cell is, briefly, the yeast manufacturer's object.

Brewer's yeast is unsuited to the present day requirements of bread making, mainly by reason of its poor keeping qualities, comparative slowness in fermentation, and the slightly bitter flavour and darker colour which it imparts to the loaf.

There are to be found in the botanical world numerous storehouses and reserves of sacchariferous material which are well suited to the yeast maker's requirements. The use of some of the materials mentioned below is still in the experimental state, but a closer examination into their suitability for yeast-making should prove profitable, particularly in view of the world shortage of cereals, which is bound to adversely affect the conduct of the yeast manufacturer's business for many years to come.

In addition to barley, wheat, rye, oats, and maize, both malted and unmalted, there are also used buckwheat, potatoes, beet, and cane molasses, tapioca, sago, rice, malt coombs, bran, locust beans, cotton seed, artichokes, dates, and many varieties of beans and seeds capable of yielding either sugar or nitrogenous food stuff, or both, after suitable treatment.

Tapioca and sago have already proved most satisfactory substitutes for the more costly maize, whilst Sudan dhurra, date, and sand locust beans are plentiful and relatively cheap.

Barley is malted much as in brewery maltings, except that the condition of flooring must conduce to the greatest possible production of diastase, followed by such kiln heats as will not cripple the enzyme. It is not difficult by the use of an excess of warm dry air to produce a tender friable malt high in diastatic power. Such malts contain from 12 to 15 p.c. of moisture. Small heavy barleys are usually chosen, and preferably those yielding a large percentage of soluble uncoagulable albuminoids, such, for example, as Danubian and Russian. In Scotland a large proportion of home grown barley is used.

Green malt, that is, unkilned malt, is not infrequently used. Such malt at the end of the withering stage is passed through a machine containing rollers and mixers converting it

(with the aid of a little water) into 'malt milk,' which may be mashed along with the other materials as described below. Wheat, oats, and rye may be used either malted or unmalted. Maize may be used in the form of grits, but usually a meal from the entire corn is employed. The maize meal is sometimes simply mixed with the malt, &c., in the course of mashing, or it may be subjected to treatment in the mash tun before adding the bulk of the malt and the other ingredients, or, as is most usual, separate converters may be employed.

A form of converter, much commoner on the Continent than in this country, consists of a long inverted cone, provided with a dome-shaped cover, and designed to withstand considerable pressure. The maize, either entire or cracked into three or four pieces, is introduced, and after a preliminary soaking and steaming is subjected to considerable steam pressure which completely loosens up the whole texture. This accomplished, steam is turned into the space beneath the dome cover, and a comminuting or grid valve opened at the apex of the cone. The gelatinised mass is blown violently through this valve, thus completing its disintegration.

Open converters, consisting only of a wooden vessel provided with a powerful rake, are also used. In this case the maize must be ground to a fine meal, gelatinised and liquified by malt, as in brewery working. Potatoes are commonly used on the Continent. They are washed, sliced, and converted into a pulp. Beet and artichokes are treated similarly. Malt coombs and bran are of use as providing valuable assimilable nitrogenous food stuff for the yeast, whilst their value in assisting drainage of the mash must not be overlooked.

The methods employed in individual European yeast distilleries vary so widely that it will be better to give a more or less detailed account of two of the commoner methods rather than attempt a general description intended to cover all the methods in use. A preliminary process common to most methods is the making of 'bub.' It is well-known that one explanation of the fact that micro-organisms living in a medium favourable to their development will cease reproduction long before the available food supply is exhausted is to be found in the fact that their excretory products or the by-products of their vital processes are poisonous to them and exert an inhibitory effect on their development.

Now the distiller in fermenting an unboiled, and consequently unsterilised, wash at temperatures above 80°F. is likely to be faced with an enormous development of the organisms producing lactic and butyric acids. The butyric organism in particular is undesirable, on account of the characteristic odour and taste of rancid butter which accompanies its growth. Undue development of such disease organisms not only reduces the vigour and keeping properties of the yeast, but results also in great loss of alcohol. The development of these deadly organisms may be prevented if there is already present in the wash a small amount of lactic acid. Very small amounts of lactic acid suffice to prevent the growth of both the lactic and butyric organisms. To produce the acid, a small portion, say 5 p.c. of the total raw material,

is mashed at a suitable temperature in a small vessel, known as a bub tun, and after a suitable saccharifying period the mash is cooled to 120°F., which is about the optimum temperature for the lactic organism, and the whole allowed to become sour. The souring may be produced by adding a pure culture of the lactic organism or by adding a few gallons of bub reserved from a previous operation. After a further stand this sour mash, now known as bub, is added to the main mash which would itself rapidly become sour. Previous to separating the wash from the grains the mash would require to be raised to say 160°F., in order to kill the acid producing bacterium. Instead of acidifying the whole mash, a rough extract from the bub may be added after sterilisation to the fermenting tun or wash back prior to fermentation. Some distillers make a practice of keeping the acidified main mash at a temperature of 125°F. for many hours, it being thought that lactic acid has a peptonising or digestive action on some of the insoluble albuminoids, thereby converting them into readily assimilable yeast food. It is improbable that any such peptic action takes place, and the benefit to be derived from the introduction of the lactic organism lies in the security it affords against unrestrained multiplication of acid-producing organisms in the fermenting tun. It has been suggested that a like degree of protection may be obtained by the use of commercial lactic acid, thus obviating the dangers attendant on the encouragement of bacterial growths on distillery premises and also in effecting a great saving of time. Commercial lactic acid has, however, proved a failure, although the suitability of certain mineral acids has been demonstrated.

In yeast making, a water comparable in many respects with that from the London clay is generally regarded as most suitable. The yeast manufacturer strives to obtain the greatest possible extract from his materials, and to that end a soft extractive water is decidedly an advantage, whilst the presence in considerable quantities of the chlorides of calcium and sodium undoubtedly contributes to the fermentability of the wash and so to the yield of yeast obtained.

Waters containing nitrates, nitrites, and other salts known to exert a harmful influence on yeast, would naturally be rigorously excluded. The biological purity of the water should claim the yeast manufacturers' attention, since that complete sterilisation afforded to the brewer in his copper is not available to the distiller. A thorough boiling with subsequent sedimentation is as far as most yeast manufacturers go in the matter of liquor treatment.

The Main Mashing Operation.

Distillery mash-tuns are remarkable for their great size. They are usually of cast iron, and some may possess a false bottom whilst others have no false bottoms, filtration being effected by the aid of filter presses; or both these means of filtration may be employed in conjunction. In some cases coarse sieves only are found. An extremely powerful rake or rouser is necessary.

The two methods of yeast manufacture to

be described are known respectively as the Vienna process and the air-yeast process. The grist, or raw material, which has been finely ground, may consist of from 15 to 25 p.c. of malt, 50 to 80 p.c. of maize treated separately, and about 20 p.c. of either barley, oats, rye, and wheat, or a mixture of any or all of these cereals. Equal proportions of malt, maize, and rye form a not uncommon mixture. An American yeast factory uses 30 p.c. barley malt and 35 p.c. each of maize and rye. The ground malt together with the finely ground raw cereals which should be kiln dried is mashed with water of such a temperature as to give a final or mixture heat of 125° to 130°F. The maize 'conversion' may now be run in at such a temperature as to raise the whole mash to perhaps 135°-140°F. The rakes would be running the whole operation. Steam or hot water may now be injected, raising the mash to 150°F. The total quantity of water used would be at the rate of 35 to 40 gallons per 100 lbs. of grist or raw material. A suitable 'standing on' completes the operation. The addition of 'bub' at some convenient stage has already been referred to.

The methods up to this point would probably not differ greatly in either of the two processes mentioned, namely 'Vienna,' and 'air-yeast,' but from this point there is a pronounced divergence, inasmuch as with the Vienna process the actual mash itself, cooled, and perhaps slightly diluted, is fermented. The entire mash is transferred to fermenting vessels, and sufficient yeast to ensure an early and vigorous fermentation is added. The yeasty heads push their way through the grains, and are skimmed off by hand. Such skimmings are then passed through sieves of fine bolting silk, which separate the yeast from the grains, the yeasty washings being collected in settling tanks. The course of the fermentation is described below. The yield of yeast from this process is small, as, apart from other considerations, some 15-20 p.c. of the yeast produced escapes the sieving and passes to waste with the grains. The Vienna process results in high spirit yields but the yeast is often weak.

In the 'air-yeast' method the mash after standing a few hours is passed to filter presses; which effect the complete separation of the 'grains' from the liquid extract or wash. The wash is collected in wood or wrought-iron vessels usually fitted with tempering coils, and provided with a star-shaped arrangement of perforated iron or copper pipes lying on the bottom through which air can be forced.

The specific gravity of the wash before fermentation varies from 1030° to 1040°. A pitching temperature of say 75°-78°F. is aimed at and yeast added in sufficient quantity to ensure a very active fermentation immediately setting in. Throughout the whole course of fermentation, except in certain special cases, a current of air is blown through the wash, giving the tun the appearance of being gently on the boil. Aëration is of greatest importance during collection of the wash, that is to say, during the periods immediately anterior to and subsequent to the addition of the seed yeast. Aëration throughout the whole course of fermentation effects the removal of the large quantities of CO₂ produced, thus leaving an

fettered the reproductive capacity of the yeast organism, whilst the passage of a strong air current also effects both mechanically and by volatilisation the removal of some of the alcohol. Possibly also yeast metabolism is assisted by the presence of an ample supply of oxygen. Undoubtedly the very complete mechanical intermixture of yeast and wash ensured by the passage of the air current increases the amount and the rate of attenuation.

Two typical fermentations are given below :—

No. 1, 28 hours			No. 2, 10 hours		
Time	Sp gr	T°	Time	Sp gr	T°
Midnight .	38	76	Midnight .	30.0	79
6 a.m. .	32	78	1 a.m. .	29.0	80
Noon .	20	82	2 .. .	27.0	82
6 p.m. .	10	84	3 .. .	23.0	84
Midnight .	4	86	6 .. .	14.5	86
4 a.m. .	2	86	7 .. .	10.0	86
			9 .. .	3.5	86
			10 .. .	1.5	86

No. 1 was a top fermentation in which a portion of the yeast was removed by means of mechanical skimmers, and No. 2 represents a bottom yeast without removal during fermentation. In the air process the separation of the yeast from the wash is variously effected but commonly by means of centrifugal separators, which produce a thick creamy yeast suitable for pressing into cakes by means of a yeast press. The cakes are broken up and packed into the well-known 7 and 14 lb. jute bags.

Yield of Yeast.

The weight of pressed yeast produced is usually referred to the weight of the grist, and a yield of 20–22 p.c. of pressed yeast is expected in most British distilleries. Continental manufacturers claim to have obtained a yield of 50 p.c.

A yield of 35 p.c. is not difficult to obtain, but the quality of the yeast is poor. The American yeast factory already referred to produces only 12½ p.c. of yeast using the Vienna process, whilst a certain Continental yeast factory produces 20 p.c. of yeast by the Vienna process, and 35 p.c. by the aëration method. It used to be common to add a proportion of potato starch to the yeast before pressing, probably with a view to increasing its dryness and consequent keeping property, but the practice is discontinued. Pressed yeast packed in bags leaves the factory containing about 70 p.c. of moisture.

Both 'top' and 'bottom' yeasts are employed, the characters of the particular races found suitable, being preserved by the aid of pure culture apparatus. The absence of any effective sterilisation during wash preparation renders it difficult to preserve a pure yeast for any such lengthy periods as are common in well conducted breweries, and frequent replacements of the pitching yeast are necessary. The method of pure culture follows closely the principles and practice as laid down by Hansen and his co-workers. Valuable by-products resulting

from the manufacture of pressed yeast are alcohol and grains. The alcohol is recovered from the fermented wash, after removal of the yeast, by distillation. Many types of distilling apparatus are in use, the usual type in Great Britain being the Coffey still, in which raw steam is blown through the wash, thereby effecting the removal of the alcohol. The resulting mixture of steam and alcohol vapour is fractionally condensed.

The differences between Vienna and air-yeast methods occasion some modification in the type of still used, as, in the Vienna process, it is not usual to separate the grains from the fermented wash before recovering the alcohol. In the air-yeast process the liquid passed to the still is practically free from suspended matter—certainly no particles of grain are present sufficiently large to block the passage of the wash through the perforated copper plates used in the Coffey still.

In the Vienna process a yield of 6½ gallons of 90 p.c. alcohol per cwt. of grist may be obtained, whilst in air-yeast distilleries the yield per cwt. probably will not exceed 5½ gallons of 90 p.c. alcohol.

Yields of yeast and spirit are roughly inversely proportionate, as the following figures, giving two examples of the two common methods, will show :—

Method	Vienna		Air process	
Yeast, per cent. .	12.5	20.0	22.0	35.0
Spirit, galls. per cwt. of proof spirit .	6.0	6.8	5.8	4.0

The spent grains resulting from the manufacture are usually dried, when they may be sold for cattle food, or they may be mixed with sludge from the fermenting vessels, sweetened with molasses and pressed into cakes.

In some distilleries also the large quantity of carbonic acid gas produced is collected and compressed into steel tubes for use commercially.

For methods of detecting the presence of brewer's yeast in pressed yeast, see Vautier, Ann. Chim. anal. 1919, 1, 345; J. Soc. Chem. Ind. 1920, 38 A.

YELLOW CEDAR. The *Rhodospheera rhodanthema* (Engl.) or yellow cedar, a tree growing to the height of 70 or 80 ft., is indigenous to the northern part of New South Wales.

The colouring matter of this dyewood is *fisetin*, which is readily isolated by the method described in connection with Young Fustic (Perkin, Chem. Soc. Trans. 1897, 71, 1194).

A second substance $C_{20}H_{20}O_{11}$, colourless

needles, m.p. 215°–217°, is also present in small amount, and may be identical with *fustin*, the glucoside of *fisetin* (Schmid, Ber. 1886, 19, 1755).

The shades given by the yellow cedar are slightly weaker and differ considerably from those given by young fustic (*Rhus Cotinus*), although both contain the same colouring matter. Employing mordanted woollen cloth, the following distinctions are observed—

	Chromium	Aluminium	Tin	Iron
Young fustic .	Reddish brown	Orange	Orange yellow	Brown olive
Yellow cedar .	Yellowish brown	Brownish yellow	Golden yellow	Olive yellow

and these may be due to varying amounts of a brown extractive matter, which is contained in both plants. A. G. P.

YELLOW WALLFLOWER (*Cheiranthus cheiri*). The purplish-brown petals of the common garden wallflower are comparatively rich in colouring matter, though the shade given by these on alumina mordant possesses a greenish-olive-yellow tint, and is of a less pure character than that given by the variety known as 'Cloth of Gold.' A boiling aqueous extract of these latter flowers on treatment with sulphuric acid gradually deposits a yellow precipitate, and this is most readily purified by pouring the concentrated alcoholic solution into much ether. The main impurity is thus precipitated, whereas the colouring matter remains dissolved in the ether. By fractional crystallisation from alcohol two colouring matters can be isolated from this extract: (a) *amaranthine* soluble in water, and (b) *guercetin*. The existence of isorhamnetin was first demonstrated by an examination of these flowers (Perkin and Hummel, Chem. Soc. Trans. 1896, 69, 1566). A. G. P.

YELLOW WOOD v. OLD FUSTIC.

YENITE, v. ILVAITE.

YEW (*Taxus*; *If commun*, Fr.; *Eibe*, Ger.). It has long been known that the leaves and berries of the common yew, *Taxus baccata* (Linn.), (Bentl. and Trim. 253), possess powerful toxic properties. Yew is a reputed emmenagogue, and it has been used for the purpose of procuring criminal abortion, but its efficiency is more than doubtful, and its employment often leads to fatal consequences (cf. Redwood, Pharm. J. [iii.] 8, 361). The contraction of the uterus is probably reflex, as a result of the irritation of the intestine by the essential oil (Meyer and Gottlieb, Experimentelle Pharmakologie, 1914, 213). The first thing to do in cases of poisoning is to empty the stomach; milk may then be given to allay irritation, and such stimulants as alcohol or ammonia employed. Yew is seldom used in medicine.

Chevallier and Lassaigne (J. Pharm. Chim. 1818, 4, 558), Peretti (*ibid.* 1828, 14, 537), Lucas (Arch. Pharm. [ii.] 85, 145), and others have examined yew chemically, but no definite compound was isolated till the discovery of an alkaloid *taxine* by Marmé in 1876 (Chem. Zentr. 1876, 166). Taxine was further studied by Amato and Capparelli (Gazz. chim. ital. 10, 349), who also obtained a non-nitrogenous crystalline compound *milossin*, and a *volatile oil* which distils with steam, and has the odour of fennel. The chemical reactions of taxine obtained by Marmé's process have been examined by Hilger and Brande (Ber. 1890, 23, 464). Taxine is prepared by exhausting yew leaves or seeds with alcohol or ether. The residue, after distilling off the alcohol or ether, is extracted with acidified water, and from the clear aqueous solution alkalis precipitate the base in white flakes, which, when washed and dried over sulphuric acid, assume the appearance of a white crystalline powder. The leaves, when dry, contain 0.7–1.4 p.c. of alkaloid, the seeds less. Leaves which have been preserved without preliminary drying yield very much less alkaloid. The preliminary extractions of the leaves with alcohol or ether may be dispensed with; they can be treated directly with a weak solution of an acid. Thorpe and Stubbs (Chem. Soc. Trans. 1902, 81, 874) have investigated the conditions under which taxine can be extracted. They find that it undergoes change with extreme ease during the process of extraction, thus accounting for the difference in the description of its properties by earlier investigators. The method of extraction giving the best results was found to be treatment with dilute sulphuric acid (1 p.c.) in the cold. Taxine, so obtained, consists of very fine glistening particles or a white amorphous powder. It does not crystallise. It is odourless, but possesses a very bitter taste. It is very slightly soluble in water, is soluble in dilute acids, alcohol, ether, benzene, or chloroform, and insoluble in light petroleum. At 82° taxine practically melts, undergoing at the same time some decomposition. Analysis gives

proposed by Hilger and Brande. Taxine gives reactions characteristic of the alkaloids when treated with the usual reagents, and also combines with acids to form definite salts, which have, however, not been obtained crystalline. From the residue, insoluble in very dilute acids, after the removal of the taxine, alcohol and animal charcoal extract milossin. Its purification is tedious and difficult. It crystallises in stellate groups of needles, which melt at 86° – 87° , and which are insoluble in water, but soluble in boiling alcohol (Amato and Caparelli).

A glucoside, *taxicatin*, has been found in the leaves of the yew by Bourquelot (J. Pharm. Chim. [vi.] 1906, 23, 369). Taxicatin $C_{18}H_{22}O_7$, crystallises from alcohol in colourless needles, m.p. 169° – 170° (corr.); the crystals obtained from aqueous solutions contain $2H_2O$. It is hydrolysed by emulsin or by 2 p.c. sulphuric acid into dextrose and a substance readily soluble in ether or chloroform (Lefebvre, *ibid.* [vi.] 1907, 26, 241).

The twigs of *Taxus baccata* were found to contain invertin and emulgin (Lefebvre), and raffinose and sucrose have been isolated from the leaves and twigs (Hérissey and Lefebvre, *ibid.* [vi.] 1907, 26, 56).

The leaves of yew have been further examined by Winterstein and Iatrides (Zeitsch. physiol. Chem. 1921, 117, 240). With colloidal platinum taxine takes up four atoms of hydrogen; it also takes up four bromine atoms. Acid hydrolysis yields cinnamic and acetic acids and an amorphous substance reducing Fehling's solution. Taxine forms a methiodide $C_{27}H_{51}O_{10}N \cdot CH_3I$ and a tri- or tetra-acetyl derivative. Similar results were obtained by Kondo and Amano (J. Pharm. Soc. Japan, 1922, No. 490, 1074; Chem. Soc. Abstr. 1923, i, 361; J. Soc. Chem. Ind. 1923, 290 A.). An alcoholic extract, treated with ammonia yielded a precipitate of taxine, as a white amorphous powder, $C_{27}H_{51}NO_{10}$, sintering at 82° and melting at 105° – 111° ; $[\alpha]_D^{18} = +32^{\circ} 20'$, and 35° for 5 and 10 p.c. alcoholic solutions respectively. By warming with 5 p.c. sulphuric acid, the alkaloid was partly decomposed, a compound reducing Fehling's solution being produced which was, however, not a sugar. On warming with alcoholic potash taxine was decomposed into formic and acetic acids, an amorphous acid of m.p. 94° – 95° , and mol. wt. 215, a crystalline acid (perhaps cinnamic acid), m.p. 133° , and a compound $C_{22}H_{33}NO_4$, m.p. 105° – 110° , insoluble in dilute sulphuric acid. By brominating in glacial acetic acid, the alkaloid gave a tetrabromide $C_{27}H_{41}NO_{10}Br_4$, yellow amorphous powder, while in dilute sulphuric acid a tribromide $C_{27}H_{41}NO_{10}Br_3$, or $C_{27}H_{41}NO_{10}Br_2 \cdot HBr$, light yellow amorphous powder, was produced.

The amount of taxine present in the Irish yew, *Taxus baccata*, var. *fastigiata*, has been investigated by Mons (Sci. Proc. Roy. Dubl. Soc. 12, 92). The results seem to indicate that the Irish yew contains much more taxine than the common yew.

G. B.

YLANG-YLANG : OILS, ESSENTIAL.

The ylang-ylang and cananga oil are obtained from the *cananga odorata*, but the blossoms of the *cananga latifolia* are also used for distillation. These two oils are the most valuable perfumes

of the tropics, but there is an essential difference between them, and their quality varies according to the land of their origin, probably on account of the more or less primitive distillation methods and the greater or smaller care observed in the collection of the blossoms. On the island of Réunion a full-grown cananga tree bears 10 to 15 kilograms of blossoms, and in rare cases 40 to 50 kilograms. This means a blossom harvest of about 2,000 kilograms per hectare. The trees bloom in January, and the best yield of oil is obtained in May and June, or later. Gathered just before the anthesis, the blossoms are subjected to distillation in as fresh a state as possible. The best ylang-ylang oil is furnished by the first fractions, while the rest of the distillate consists of cananga oil. In the Bantam districts of Java this inferior oil is obtained from the crushed blossoms which are distilled with water, but without sufficient cooling. The yield varies between 1.5 and 2.5 p.c., while the first fractions, which represent a prime distillate, only amount to 1 p.c. The clear, amber-coloured ylang-ylang oil is very sensitive to the influence of light and oxygen, and its composition is highly complicated. So far, the presence of the following substances in the oil has been definitely established: Benzoic and acetic acids (the formic acid sometimes found seems to be an impurity), linalool, geraniol, paracresol, methyl ether, cadinene, a pinene, a phenol, saffrol, isosafrol, nerol, farnesol, eugenol and isoeugenol, eugenic acid methyl ester, benzyl acetate and benzoate, anthranilic and salicylic acid methyl esters, and a sesquiterpene alcohol. The cananga oil is richer in sesquiterpenes, but poorer in esters, and the javanese varieties contain nerol and farnesol. About 2,000 kilograms of Manila-ylang were exported in 1920 from the Philippine Islands. The first ylang oil was distilled on the island of Luzon in the 'sixties of the last century (Deutsche Parfümerie-Zeitung, through Amer. Perf. and Ess. Oil Rev. February, 1924, 629; Pharm. J. 1924, 112, 334).

YOGHURT. A preparation of sour milk made in Bulgaria and Turkey by the action of the *Bacillus bulgaricus* and other micro-organisms, giving rise to a mixture of dextro-rotatory and lævo-rotatory lactic acid, the former predominating.

YOHIMBINE (=Quebrachine) $C_{21}H_{23}O_2N_2$ occurs along with other alkaloids in yohimbe bark of *Corynanthe yohimbe*, K. Schum = *Pausinystalia yohimbe* (K. Schum) Pierre, N. O. Rubiaceae, which occurs in the Cameroons and other parts of West Africa. False yohimbe bark of *C. macroceras*, K. Schum = *P. macroceras* (K. Schum), Pierre contains very little yohimbine, but a considerable quantity of other alkaloids. Yohimbine is further present in *P. Trillesii*, Pierre. These species are related to the genus *Cinchona* of the same order. For an account of the anatomical characters of true and false barks, with illustrations, see Small and Adams (Pharm. J. 1922, 108, 282, 311), who also give an account of the literature. Yohimbe bark is used by the natives as an aphrodisiac, and the alkaloid yohimbine, patented by Spiegel in 1896 (Chem. Zeit. 1896, 20, 970; 1897, 21, 833; 1899, 23, 59, 81; Ber. 1903, 36, 169; 1904, 37, 1759; 1905, 38, 2825), is now used for

the same purpose, chiefly in veterinary medicine. Spiegel considers that yohimbine has the composition $C_{21}H_{26}O_2N_2$, but a detailed study by Fourneau and Fiore (Bull. Soc. chim. 1911 [iv.] 9, 1037), and by Fourneau and Page (Bull. Sci. Pharmacol. 1914, 21, 7) have established the formula $C_{21}H_{26}O_2N_2$ and the identity of yohimbine with quebrachine, isolated from the bark of *Aspidosperma Quebracho-blanco*, Schlecht. by Hesse, in 1882. This identity was confirmed by Ewins (J. Chem. Soc. 1914, 105, 2738), so that, except for practical reasons, the name yohimbine should not be retained. The formula $C_{21}H_{26}O_2N_2$ is also supported by Miss Field (J. Chem. Soc. 1923, 123, 3003). Spiegel (Ber. 1915, 48, 2077) maintains that this formula belongs to another alkaloid, *mesoyohimbine*, m.p. 247°, also present in the bark.

Yohimbine crystallises in needles, m.p. 234° (Spiegel), 247°–248° (Fourneau and Page). The melting-point varies considerably with the rate of heating. Yohimbine sublimes at 210°–220°/8 mm., and has $[\alpha]_D^{20} +56.0^\circ$ in alcohol. The hydrochloride $C_{21}H_{26}O_2N_2 \cdot HCl$ has m.p. 302°–303°, $[\alpha]_D^{20} +106.4^\circ$ in water; the sulphate $(C_{21}H_{26}O_2N_2)_2 \cdot 8H_2O$, m.p. 281°–282° (anhydrous), and $[\alpha]_D^{20} +100^\circ$ in water. The hydrochloride and particularly the nitrate are sparingly soluble in water. The colourless solution of the alkaloid in concentrated sulphuric acid becomes violet and then green on stirring in a crystal of potassium dichromate. Yohimbine is a monacid tertiary base, and the monomethyl ester of a hydroxy acid derived from indole (and quinoline?). Hydrolysis with alkali yields *yohimbic acid* $C_{20}H_{24}O_4N_2$, an amphoteric substance, soluble in hot water, m.p. 257°–260°, on the composition of which all authors agree. It can be re-esterified with methyl alcohol and hydrogen chloride to yohimbine (e.g. Field, l.c.), and with other alcohols to homologues of yohimbine. Two oxygen atoms of yohimbine are therefore present in a carboxyl group; the third is in a hydroxyl, which is esterified when yohimbine is dissolved in cold concentrated sulphuric acid (Barger and Field, J. Chem. Soc. 1915, 107, 1025; 1923, 123, 1038). When the solution is poured on ice *yohimbine sulphuric ester* separates, which, crystallised from 1400 parts of boiling water, forms needles, m.p. 292°–295°. This characteristic derivative is also formed from quebrachine (Ewins). When it is warmed with dilute sodium hydroxide, *apoyohimbine* separates $C_{21}H_{24}O_2N_2$, m.p. 251°–252°, $[\alpha]_D = +40^\circ$; this unsaturated base has a very sparingly soluble hydrochloride (1 : 1300 in water at room temperature), and can be reduced catalytically to *deoxy-yohimbine*

(Barger and Field).

For the determination of yohimbine in the bark, see Schomer, Pharm. Zentralh. 1922, 63, 385; for the physiological action, Oberwarth, Virchow's Archiv. 1898, 153, 292; F. Müller, Arch. f. Anat. Physiol., Physiol. Abt. 1906, 391; Gunn, Quart. J. exp. Physiol. 1908, 1, 111; Tait, ibid. 1910, 3, 185; Rumry, J. Pharm. exp. Ther., Proc. 1918, 11, 172). G. B.

VOL. VII.—7.

YOUNG FUSTIC. Young fustic consists of the wood of the stem and larger branches of the *Rhus cotinus* (Linn.), a small tree which is a native of Southern Europe and the West India Islands. It is a hard compact yellow wood, and is usually imported in small bundles or faggots. Within the last few years young fustic has almost disappeared from the market, not only on account of the artificial colouring matters, but because the shades it yields lack permanence, and the percentage of colouring matter it contains is small. The leaves of the *R. cotinus* constitute Venetian sumach, a tanning material which is employed to some extent in Italy and Southern Europe.

Fisetin $C_{15}H_{10}O_6$, the colouring matter of young fustic, was first isolated by Chevreul (Leçons de Chimie appliquée à la Teinture, A. ii. 150), who gave it the name 'Fustin.' Bolley (Schweiz. polyt. Zeitschr. 1864, 9, 22) considered that it was identical with quercetin, but Koch (Ber. 5, 285) maintained that fisetin was probably an aldehyde of quercetin acid.

Schmid (Ber. 1886, 19, 1734), who carried out an exhaustive examination of this dyewood, obtained fisetin in a pure condition and proved that it was not identical with quercetin. He found that in addition to the free colouring matter, young fustic contains a glucoside of fisetin combined with tannic acid to which he gave the name of *fustin tannide*.

To prepare fisetin, Schmid (l.c.), and later Herzig (Monatsh. 12, 178), employed 'cotinin' (v. infra), a commercial preparation of young fustic which is no longer on the market. According to Perkin and Pate (Chem. Soc. Trans. 1895, 67, 648), fisetin is readily isolated from the dyewood as follows:—

Young fustic is extracted with boiling water, and the extract treated with lead acetate solution. The lead compound of the colouring matter is collected, made into a thin paste with water, and in a fine stream run into boiling dilute sulphuric acid. After removal of lead sulphate the dark-coloured filtrate, on cooling, deposits a semi-crystalline brownish mass, which is collected and purified by crystallisation from dilute alcohol.

Schmid assigned the formula $C_{23}H_{14}O_6$ to fisetin, but it was found by Herzig that the analyses agreed equally well with $C_{15}H_{10}O_6$, and that this formula was correct was supported by the work of Perkin and Pato (l.c.), who gave to fisetin sulphate the formula—

Fisetin forms yellow needles, melting at above 360°, easily soluble in alcohol. Alkaline solutions dissolve it with a deep yellow colour which, on exposure to air, gradually changes to brown; with alcoholic ferric chloride it gives a deep green coloration, and with lead acetate a bright orange-red precipitate. *Tetra-acetyl-fisetin* $C_{15}H_6O_8(C_2H_5O)_4$, m.p. 196°–198°, crystallises in colourless needles, and the *benzoyl* derivative $C_{15}H_6O_8(C_6H_5O)_4$, needles, melts at 180°–181° (Perkin and Pato), (Schmid, 184°–185°). Fisetin gives with mineral acids in the presence of acetic acid crystalline salts. *Fisetin sulphate* $C_{15}H_{10}O_6 \cdot H_2SO_4$, scarlet needles, *fisetin hydrobromide* $C_{15}H_{10}O_6 \cdot HBr$, orange needles, and *fisetin hydrochloride* have been prepared in this

manner (Perkin and Pate). These compounds are readily decomposed by water. *Mono-potassium fisetin* $C_{15}H_8O_6K$, yellow needles (Perkin, Chem. Soc. Trans. 1899, 75, 433), is obtained from fisetin by means of alcoholic potassium acetate.

By fusion with alkali or oxidation of its alkaline solution by exposure to air fisetin gives *resorcinol* and *protocatechuic acid* (Herzig).

On ethylation with ethyl iodide fisetin is converted into *fisetin tetraethyl ether*

colourless needles, m.p. $106^\circ-107^\circ$; the corresponding methyl derivative $C_{16}H_{14}O_6(OC_2H_5)_4$ melts at $152^\circ-153^\circ$.

When fisetin tetraethyl ether is submitted to the action of boiling alcoholic potash it gives *protocatechuic acid diethyl ether*, and *fisetol diethyl ether* (Herzig), colourless needles, m.p. $42^\circ-44^\circ$. This latter compound, by oxidation with permanganate, is converted into the *monoethyl ether of resorcylic acid*, and the *monoethyl ether of resorcinolglyoxylic acid*, and consequently fisetol diethyl ether may be thus represented—

As a result of his investigation Herzig assigned to fisetin the constitution of a *tri-hydroxyflavonol*—

The tetraethyl derivative of this compound suffers hydrolysis according to the following scheme:—

Fisetin has been synthesised by v. Kostanecki, Lampe, and Tambor (Ber. 1904, 37, 784).

2-Hydroxy-4-ethoxy-3':4'-dimethoxychalkone (1)—

prepared by the condensation of resacetophenone monoethyl ether with veratric aldehyde, when digested with boiling dilute alcoholic sulphuric

acid gives 3-ethoxy-3':4'-dimethoxyflavonone (2)—

and this, when treated with amyl nitrite and strong hydrochloric acid in alcoholic solution, is converted into the isonitroso compound (3)—

When boiled in acetic acid solution with 10 p.c. sulphuric acid this substance gives 3-ethoxy-3':4'-dimethoxyflavonol (4), from which fisetin (5) is readily produced by the action of boiling hydriodic acid—

The synthesis of fisetin has been more recently effected by Auwers and Pohl (Ber. 1915, 48, 85), from *m-p*-dimethoxy-benzylidene-6-methoxy-cumaranone, the yield being, however only 5 p.c.

Fisetin is a strong colouring matter and gives shades which are almost identical with those produced by quercetin, rhamnetin, and myricetin. The colours given with wool mordanted with chromium, aluminium, and tin are, respectively, red-brown, brown-orange, and bright red-orange (Perkin and Hummel, Chem. Soc. Trans. 1890, 69, 1290).

The glucoside of fisetin, according to Schmid (l.c.), is prepared as follows: A boiling aqueous extract of young fustic is treated with lead acetate, the precipitate removed, the clear liquid freed from lead by means of sulphuretted hydrogen, and saturated with salt. The mixture is filtered, the filtrate extracted with ethyl acetate, and the extract evaporated. There is thus obtained a residue consisting of the crude fustin-tannide, which is purified by solution in water, precipitation with salt, and extraction with ethyl acetate.

Fustin tannide crystallises in long yellowish-white needles, which are easily soluble in water, alcohol, and ether. When heated it decomposes above 200° . If a solution of fustin tannide in hot acetic acid is treated with water, and allowed to stand for some time, colourless crystals of *fustin* are gradually deposited.

Fustin crystallises from water in yellowish-white needles, m.p. $218^\circ-219^\circ$, and when digested with boiling dilute sulphuric acid gives *fisetin* and a sugar, the nature of which has not been determined. The formula given to this glucoside $C_{28}H_{24}O_{18}$ by Schmid cannot be regarded as correct, in view of the fact that the true formula of fisetin is now known to be $C_{15}H_{10}O_6$.

Dyeing properties of young fustic.—The colours derived from young fustic are all fugitive to light, hence this dyestuff has lost its importance. In silk dyeing it was formerly used for dyeing brown, the silk being mordanted with alum, and afterwards dyed with a decoction of young fustic, peachwood, and logwood. With the various metallic salts as mordants young fustic yields colours somewhat similar to those obtained from old fustic, the chromium colour is, however, much redder, being a reddish-brown, and the aluminium yellow is much duller; stannous chloride on the contrary gives an incomparably more brilliant orange, not unlike that obtainable from flavin or from Persian berries (Hummel).

Fisetin is present also as glucoside in the wood of the yellow cedar, *Rhodospachra rhodanthema*, and in the wood of the *Quebracho colorado* (l.c.).

The leaves of the *R. cotinus* contain myricetin.

A. G. P.

YPERITE. Syn. for $\beta\beta'$ -dichloroethyl sulphide; 'mustard gas' (q.v.). For a method of detecting and estimating yperite, see Grignard, Rivat and Scatchard, Ann. Chim. 1921, [ix.] 15, 5.

YTTERBIUM (*Neoytterbium*; *Aldebaranium*; *Cassiopaeum*). Sym. Yb. At.wt. 173.5. In 1878 Marignac, by the fractional decomposition of the nitrates, isolated from crude erbia the earth *ytterbia*, which has since been resolved by Urbain into two components *neoytterbia* and *lutecia* (Compt. rend. 1907, 145, 759; cf. Auer von Welsbach, Monatsh. 1906, 27, 935; 1908, 29, 181; 1913, 34, 1713; Wenzel, Zeitsch. anorg. Chem. 1909, 64, 119; Urbain, Chem. Zeit. 1908, 32, 730; Blumenfeld and Urbain, Compt. rend. 1914, 159, 323).

Occurrence.—Is found in xenotime, ytterbite (gadolinite), monazite.

Separation and purification. v. LUTECIUM (cf. Urbain, Congress of Applied Chemistry, 1909, x. 94).

Ytterbium oxide (*Ytterbia*) Yb_2O_3 , a colourless mass when free from thulia; it dissolves slowly in cold, and readily in hot, dilute acids. With the exception of scandia and lutecia, *ytterbia* (*neoytterbia*) is the weakest base of the yttrium earth series.

Ytterbium hydroxide $\text{Yb}(\text{OH})_3$ is a colourless gelatinous precipitate.

Ytterbium chloride $\text{YbCl}_3 \cdot 6\text{H}_2\text{O}$ (Matignon, Ann. Chim. 1906, [viii.] 8, 440), prepared by the action of hydrochloric acid on *ytterbia*, separates in deliquescent crystals, m.p. 150° – 155° ; it gives rise to the readily soluble platinum-chloride $2\text{YbCl}_3 \cdot \text{PtCl}_4 \cdot 22\text{H}_2\text{O}$, and aurichloride $\text{YbCl}_3 \cdot \text{AuCl}_3 \cdot 9\text{H}_2\text{O}$.

Ytterbium nitrate $\text{Yb}(\text{NO}_3)_3 \cdot 4\text{H}_2\text{O}$ crystallises from strong nitric acid in transparent hygroscopic prisms; a trihydrate separating in colourless plates is obtained from solutions evaporated over strong sulphuric acid.

Ytterbium sulphate $\text{Yb}_2(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$, lustrous colourless crystals, the solubility of which diminishes with rise of temperature; this salt is partially hydrolysed in dilute solutions.

Ytterbium orthophosphate $\text{YbPO}_4 \cdot 4\text{H}_2\text{O}$, a gelatinous precipitate obtained from soluble ytterbium salts and sodium phosphate; the metaphosphate $\text{Yb}(\text{PO}_3)_3$, a crystalline powder,

produced by melting together anhydrous ytterbium sulphate and metaphosphoric acid.

Ytterbium borate YbBO_3 , obtained by fusing together ytterbia and boric anhydride; is a crystalline mass insoluble in dilute hydrochloric acid.

Ytterbium carbonate $\text{Yb}_2(\text{CO}_3)_3 \cdot 4\text{H}_2\text{O}$, a gelatinous precipitate produced by mixing solutions of ytterbium nitrate and ammonium carbonate; the basic carbonate $\text{Yb}(\text{OH})\text{CO}_3 \cdot \text{H}_2\text{O}$ is formed by passing carbon dioxide through freshly-precipitated ytterbium hydroxide.

Ytterbium cobalticyanide $\text{Yb}_2(\text{CoC}_6\text{N}_6)_3 \cdot 9\text{H}_2\text{O}$, very slightly soluble in a 10 p.c. solution of hydrochloric acid; 1000 parts of a saturated solution contain 0.38 part of the salt.

Ytterbium oxalate $\text{Yb}_2(\text{C}_2\text{O}_4)_3 \cdot 10\text{H}_2\text{O}$ is a crystalline powder distinctly more soluble in dilute sulphuric acid than the oxalates of yttrium and gadolinium (Nilson, Compt. rend. 1879, 89, 419; 1880, 91, 56, 118). The normal ytterbium salts of the lower fatty acids are very soluble substances.

Ytterbium dimethyl phosphate, long white needles, solubility 1.2 at 25° and 0.25 at 95° .

Spectra.—Spark spectrum (i.) visible region (Thalén, *ibid.* 1880, 91, 326); (ii.) ultra-violet (v. Welsbach, Monatsh. 1884, 5, 1; Crookes, Proc. Roy. Soc. 1906, 78, A, 154). Spark and arc spectrum (Exner and Haschek, Die Spektren der Elemente bei normalen Druck, 1912; Eder and Valenta, Atlas typischer Spektren, 1911; Kaiser, Akad. der Wissensch. Wien).

G. T. M.

YTTRIALITE. An amorphous mineral consisting of silicate of yttrium, thorium, &c., approximating to the formula $\text{R}_2\text{O}_3 \cdot 2\text{SiO}_2$. It contains Y_2O_3 46.5, ThO_2 12 p.c. The material is translucent with a dark olive-green colour on the fresh conchoidal fracture; externally it weathers to orange-yellow. Sp.gr. 4.58, H. 5–5½; soluble in hydrochloric acid. Masses up to 18 lb. in weight are found with gadolinite at Barringer Hill in Llano Co., Texas.

L. J. S.

YTTRIUM. Sym. Y. At.wt. 88.7 (Meyer and Weinheber); 90.12 (Egan and Balke); 88.9 (Smith and Balke); 89.33 (Kremers and Hopkins); 89.03 (Fogg and James). The individuality of yttria, the predominant and most basic constituent of the yttrium earths, was first recognised by Mosander in 1843, and is the most easily purified oxide of this series.

Sources.—The yttrium earths from the following minerals: ytterbite, xenotime, fergusonite, yttrotantalite, samarskite, polycrase, euxenite, yttracrasite (Amer. J. Sci. 1906, [iv.] 22, 515). It also occurs in smaller quantities in the rare earths from cerite and allied minerals (v. CERIUM METALS AND EARTHS).

Separation and purification.—In its basicity yttria follows the more basic cerite earths and is separated by methods founded on differences in basic strength from the other less basic yttrium earths, erbia, dysprosia, thulia, ytterbia, lutecia, and scandia, the following processes being employed for this purpose: (1) decomposition of nitrates; (2) the basic salt method (v. LANTHANUM AND SCANDIUM); (3) fractional precipitation with alkalis or aniline; (4) successive treatment with ammonium carbonate and acetic acid.

Crystallisation methods are less practicable in the yttrium than in the cerium group, because of the greater solubility of the salts and the instability of the double nitrates, which in the yttrium series are unstable at the ordinary temperatures in aqueous or nitric acid solutions. Nevertheless, the final purification of yttrium from erbium, &c., may be effected by fractionation of the bromates, chromates, formates, acetates, oxalates, acetylacetones, ethyl-sulphates, and ferrocyanides (*v. ERBIUM*).

According to Meyer and Wuorinen (*Zeitsch. anorg. Chem.* 1913, 80, 7), the following methods are suitable for the fractionation of mixtures containing yttrium. The precipitation of dichromate solutions with potassium chromate separates yttrium well from terbium and gadolinium, but is most applicable to mixtures from which most of the terbium group has been removed by other methods, when it yields pure yttria.

Fractional crystallisation of the ethyl sulphates is tedious, but is suitable for large quantities. Precipitation with potassium ferrocyanide furnishes nearly pure yttria, but the yield is small, and the precipitates are not readily filtered. Crystallisation of the double ammonium tartrates is unsuccessful, as is also the fractional hydrolysis of these salts by water, ammonia, or magnesia.

A method, depending on the hydrolysis of solutions of the phthalates by heat, rapidly removes the erbium group, and gives a large yield of a product consisting mainly of yttria, which is then conveniently purified by fractionally precipitating a slightly acid solution of the nitrates with potassium iodate.

By Muthmann and Bölin's chromate method small quantities of fairly pure yttria can be rapidly prepared from mixtures containing small amounts of erbium and holmium, but the method cannot be applied to the fractionation of mixtures containing didymium and gadolinium unless these are first removed by potassium sulphate (Egan and Balke, *J. Amer. Chem. Soc.* 1913, 35, 365). Holden and James (*J. Amer. Chem. Soc.* 1914, 36, 638) have investigated the various fractional precipitation methods in order to ascertain the best method of separating yttrium from the yttrium earths. The methods used were fractional precipitation of the dimethyl phosphates, the cacodylates, the phosphates, the monomethyl phosphates, the arsenates, the phosphites, the chromates, the iodides and bromates and hypophosphates. Of these the chromate and phosphate methods were found to be the most efficient. A still more effective method has been found in the fractional precipitation with sodium nitrite. The oxides are dissolved in nitric acid, the solution diluted and boiled, and a quantity of sodium nitrite added sufficient to precipitate the required fraction of the rare earth material. The yttrium concentrates in the later fractions. This method gives a larger yield, a more rapid separation and is less expensive than the phosphate or chromate method. It is not, however, very effective for the separation of yttrium from terbium (Holden and James, *l.c.* 1914, 36, 1418).

In the fractional electrolysis of the earths from xenotime, erbium collects in the early

fractions and yttrium in the later fractions (Dennis and Lemon, *J. Amer. Chem. Soc.* 1915, 37, 31).

Willand and James (*J. Amer. Chem. Soc.* 1916, 38, 1198) find that the best modes of separating yttrium, in relatively large quantity, from erbium, are by the use of the nitrite, cobalticyanide, and phosphate methods. Fractional precipitation with sodium nitrite is recommended for work on a large scale, on account of the cheapness of the salt and the ease of manipulation (*cf.* Bonardi and James, *J. Amer. Chem. Soc.* 1915, 37, 2642; Wichers, Hopkins and Balke, *ibid.* 1918, 40, 1615).

Yttria may also be separated from other rare earths by taking advantage of its solubility in ammonium nitrate solution (Prandtl, *Zeitsch. anorg. Chem.* 1925, 143, 277).

According to Whittemore and James (*J. Amer. Chem. Soc.* 1912, 34, 773) yttrium can be quantitatively separated from sodium by precipitation with ammonium sebacate and from potassium by a double precipitation with the same reagents. The separation of yttrium from iron, aluminium, lithium, and magnesium can be effected by its precipitation as oxalate by oxalic acid in presence of ammonium chloride.

Metallurgical yttrium has been obtained by the reduction of yttrium chloride or yttrium sodium chloride with sodium or by the electrolysis of the latter salt; it is an iron-grey substance melting at 1490°, easily oxidisable and decomposing hot water (Cleve, *Bull. Soc. chim.* 1873, [ii.] 18, 193, 289; 1874, [ii.] 21, 244; *cf.* Winkler, *Bor.* 1890, 23, 44, 120, 772, 2642). *See also* *Trans. Amer. Electrochem. Soc.* 1926, 49, 161.

Yttrium oxide (*Yttria*) Y_2O_3 , white powder, sp.gr. 4.84; sp.ht. 0.1173, absorbing carbon dioxide from the atmosphere; obtained crystalline by fusion with calcium chloride (*Compt. rend.* 1888, 107, 99; *J. Russ. Phys. Chem. Soc.* 1910, 42, 96).

Yttrium hydroxide $Y(OH)_3$, gelatinous precipitate; the product obtained with ammonia in presence of hydrogen peroxide is a hydrated peroxide $Y_4O_9 \cdot xH_2O$ (Cleve, *Bull. Soc. chim.* 1885, [ii.] 43, 53).

Yttrium carbide YC_2 , yellow crystalline mass, sp.gr. 4.13, produced by heating the oxide with carbon in the electric furnace, is decomposed by water evolving acetylene, mixed with hydrogen, methane, and ethylene (Moissan and Étard, *Compt. rend.* 1896, 122, 573).

The salts of yttrium with colourless acid radicals are devoid of colour, and their solutions show no selective absorption in the visible region of the spectrum.

Yttrium fluoride $YF_3 \cdot \frac{1}{2}H_2O$ is obtained in the wet way as a gelatinous precipitate; the anhydrous substance is produced by the action of fluorine on the carbide (Moissan and Étard, *l.c.*).

Yttrium chloride YCl_3 can be produced by the methods generally applicable for the preparation of the anhydrous chlorides of the rare earths (*v. CERIUM*). The hexahydrate

colourless deliquescent prisms, melts at 100°, and is readily soluble in water or alcohol (Matignon, *Ann. Chim.* 1906, [viii.] 8, 433).

The solubilities of the chloride, bromide, nitrate, and sulphate of yttrium have been deter-

mined by Crew, Steinert and Hopkins (J. Phys. Chem. 1925, 29, 34).

Yttrium sulphate $Y_2(SO_4)_3 \cdot 8H_2O$, monoclinic crystals, isomorphous with the octahydrated sulphates of erbium, neodymium, and praseodymium (Kraus, Zeitsch. Krist. 1901, 34, 307). The acid sulphate $Y(SO_4)H_2$ separates from concentrated solutions in sulphuric acid (Braunor and Pidék, Zeitsch. anorg. Chem. 1904, 38, 322). With alkali sulphates, yttrium forms soluble double sulphates, e.g. $2Y_2(SO_4)_3 \cdot 3K_2SO_4$;

$Y_2(SO_4)_3 \cdot 2(NH_4)_2SO_4 \cdot 9H_2O$; these salts crystallise on concentrating the aqueous solution of their components.

Yttrium nitrate $Y(NO_3)_3 \cdot 6H_2O$, very soluble deliquescent crystals; a dihydrate has also been described (Tanatar and Voljanski, J. Russ. Phys. Chem. Soc. 1910, 42, 586); basic nitrates, e.g. $3Y_2O_3 \cdot 4N_2O_5 \cdot 20H_2O$, are produced by the partial decomposition of the normal salt (James and Pratt, J. Amer. Chem. Soc. 1910, 32, 873).

Yttrium phosphates. The ortho-phosphate YPO_4 , which occurs native as xenotime (*v. supra*), has been obtained in lustrous needles by melting together yttrium chloride and the amorphous phosphate ('umpt. rend. 1875, 80, 304; 1888, 107, 622). When prepared in the wet way the crystalline salt has the composition $YPO_4 \cdot 2H_2O$. The normal pyro- and metaphosphates $Y_4(P_2O_7)_3$ and $Y(PO_3)_3$ have been described together with several acid and double phosphates (Cleve, *l.c.*; Johnson, Ber. 1889, 22, 976).

Yttrium carbonate $Y_2(CO_3)_3 \cdot 3H_2O$, white precipitate obtained either from a soluble yttrium salt and an alkali carbonate, or by passing carbon dioxide into freshly-precipitated yttrium hydroxide; it dissolves in excess of aqueous alkali carbonate forming double carbonates, e.g. $Y_2(CO_3)_3 \cdot Na_2CO_3 \cdot 4H_2O$.

Yttrium cobalticyanide $Y_2(CoN_6C_6)_3 \cdot 9H_2O$. Sparingly soluble in 10 p.c. hydrochloric acid solution; 1000 parts of a sat. solution contain 2.78 parts of the salt.

Yttrium ferrieyanide $YFe(CN)_6$ is precipitated from a mixture of dilute solutions of potassium ferrieyanide and yttrium chloride.

Yttrium oxalate $Y_2(C_2O_4)_3 \cdot 9H_2O$, a white crystalline powder, dissolving in aqueous potassium oxalate to form $Y_2(C_2O_4)_3 \cdot 4K_2C_2O_4 \cdot 12H_2O$; it is soluble in dilute sulphuric acid to approximately the same extent as lanthanum oxalate.

Yttrium dimethyl phosphate, long white needles, solubility 2.80 at 25° and about 0.55 at 95°.

Yttrium salts of other organic acids (*v. Cleve, l.c.*; Tanatar and Voljansky, *l.c.*; Benner, J. Amer. Chem. Soc. 1911, 33, 50; Jantsch and Meyer, Ber. 1920, 53, [B] 1577; Meyer and Müller, Zeitsch. anorg. Chem. 1919, 109, 1).

Spectra.—Spark spectrum; visible region (Thalén, Bull. Soc. chim. 1873, [ii.] 22, 250; Bunsen, Pogg. Ann. 1875, 155, 230, 366; v. Welsbach, Monatsh. 1884, 5, 1; Meggers, J. Washington Acad. Sci. 1924, 14, 419; Meggers and Moore, *ibid.* 1925, 15, 207); ultra-violet region (Lohse, Ber. Berlin Akad. 1897, 179; Exner and Haschek, Ber. Wien. Akad. 1900, 109, IIa, 122). Arc spectrum (Exner and Haschek, Die Wellenlängen der Bogenspektren,

1904; Eberhard, Zeitsch. wiss. Photograph. Photophysik. Photochem. 1909, 7, 245; Eder, Chem. Zeit. 1916, ii. 455). A complete list of the wave lengths determined from $\lambda 2243$ to $\lambda 4200$ is given by Yntema and Hopkins (Optical Soc. of America, 1922, J. 6, 121). Cathode luminescence (Crookes, Chem. Soc. Trans. 1889, 55, 255; Chem. News, 1889, 60, 27, 39, 51, 63; Muthmann and Baur, Ber. 1900, 33, 1748; Baur and Marc, *ibid.* 1901, 34, 2460).

G. T. M.

YTTROCERITE or YTTROFLUORITE. Calcium fluoride, or fluor-spar, containing varying amounts of yttrium and cerium fluorides in isomorphous mixture or solid solution, the general formula being $(Ca, Y, Ce)_2F_6$. Artificial fusions of calcium fluoride with these rare-earth fluorides give homogeneous mixed cubic crystals containing up to 50 p.c. YF_3 (there being a maximum melting-point at 1408° with 20 p.c. YF_3 , corresponding to $7CaF_2 \cdot YF_3$), and up to 55.8 p.c. CeF_3 . The former may be called *ytthrofluorite*, and the latter *cerfluorite* (T. Vogt, 1914). Yttrocerite was originally described by Gahn and Berzelius in 1814 from Finbo and Braddbo near Fahlun in Sweden; where, as white, yellowish, or dark violet, granular masses with octahedral cleavage and sp.gr. 3.45, it occurs sparingly with topaz and albite in quartz. The early analyses showed Ce_2O_3 , 16–18, Y_2O_3 , 8–9 p.c. Similar material has been found at Amity in New York; in a fluor-spar vein in Massachusetts; at Mount Mica near Paris, in Maine; and with topaz, felspar, and quartz in Colorado (probably Pike's Peak district). The Colorado mineral is violet-blue and resembles fluor-spar in appearance; analysis showed Y_2O_3 , 29.36, Ce_2O_3 , 18.19 p.c.; sp.gr. 4.31. In 1911 T. Vogt described, as a new mineral under the name *ytthrofluorite*, material from Hundholmen in Nordland, Norway. Here it occurs in considerable quantity forming a vein some metres in width in pegmatite intersecting granite. Associated minerals are fluor-spar, orthite, gadolinite, fergusonite, and xenotime. The composition is variable, one sample yielding on analysis Y_2O_3 , 17.35, Ce_2O_3 , 1.68 p.c., corresponding nearly to the formula $7CaF_2 \cdot YF_3$ mentioned above. This material resembles fluor-spar in appearance. It is pale yellow with an imperfect octahedral cleavage; sp.gr. 3.56, H. 4½, optically isotropic, n_D 1.4572 (of the material analysed).

L. J. S.

YTTROCRASITE. Hydrated titanate of yttrium, thorium, uranium, &c., crystallised in the orthorhombic system. Analysis shows $(Y, Er)_2O_3$, 25.67, Ce_2O_3 , etc., 2.92, ThO_2 , 8.75 p.c. The mineral is black with a bright pitchy lustre on the small-conchoidal fracture, resembling polycrase in appearance. Sp.gr. 4.804, H. 5½–6. Under the microscope thin splinters are transparent and colourless to pale yellow, and are seen to consist of a mixture of optically isotropic and feebly birefringent material. The mineral thus appears to have resulted from the alteration of an originally anhydrous species. It was found in Burnet Co., Texas, not far from the well-known gadolinite locality in Llano Co.

L. J. S.

YTTROFLUORITE v. YTTROCERITE.

YTTROTANTALITE. A complex mineral

consisting essentially of yttrium tantalate and crystallising in the orthorhombic system. It is black with a bright, conchoidal fracture, and closely resembles samarskite (*q.v.*) in appearance. Masses several pounds in weight have been

found in the felspar quarries at Ytterby and Fahlun in Sweden and in the south of Norway (W. C. Brögger, *Die Mineralien der süd-norwegischen Granitpegmatitgänge*, Vid.-Selsk. Skr. Kristiania, 1906, No. 6, 152). L. J. S.

Z

ZAFFRE. *Cobalt blue v. COBALT*; also **PIGMENTS**.

ZALA. A synonym for Borax.

ZAMIA STARCH is derived from the rhizomes of *Zamia floridana*, DC., a dioecious plant belonging to the Cycadaceae growing in Florida. Is present in the air-dried rhizomes to the extent of 37-75. The grains are spherical, ovoid, and dome-shaped, varying from 6 to 40 μ in length. Sometimes marketed as 'Florida Starch,' a term also applied to the starch derived from *Maranta arundinacea*, the true arrowroot starch, also produced in Southern Florida (Clevenger, *Amer. J. Pharm.* 1922, 94, 98).

ZANTHOXYLUM. The bark of the prickly ash, *Zanthoxylum americanum* (Mill.), and *Z. carolinianum*, which are rutaceous plants. Is used in medicine in the treatment of rheumatism and to relieve toothache. It contains a volatile oil and resin.

ZARATITE or **EMERALD-NICKEL.** Hydrated basic nickel carbonate

As thin mamillary crusts with an emerald-green colour and vitreous lustre it occurs generally on serpentine together with chromite, *e.g.* at Texas in Pennsylvania, Unst in Shetlands, Dun Mountain in New Zealand, Tasmania, &c. L. J. S.

ZAUBERIN. Trade name for the sodium compound of toluene para-sulphochloramide, used as a detergent and bleaching agent.

ZEIN *v. Maize*, art. ('EREALS).

ZEIODELITE. The name of a mixture obtained by stirring 24 parts of finely-powdered glass into 20 parts of melted sulphur; used as a cement and for taking casts instead of sulphur or plaster.

ZEOBROMAL. Dibromocinnamic ethylester.

ZEOLITES. A large group of minerals consisting of hydrated silicates of aluminium with alkalis and alkaline earths. A few of the more important are—

Natrolite (<i>q.v.</i>)	$\text{Na}_2\text{Al}_2\text{Si}_2\text{O}_{10} \cdot 2\text{H}_2\text{O}$
Stilbite	$\text{CaAl}_2\text{Si}_2\text{O}_{10} \cdot 6\text{H}_2\text{O}$
Heulandite	$\text{CaAl}_2\text{Si}_2\text{O}_{10} \cdot 5\text{H}_2\text{O}$
Chabazite	$\text{CaAl}_2\text{Si}_2\text{O}_{10} \cdot 6\text{H}_2\text{O}$
Analcime	$\text{NaAlSi}_3\text{O}_8 \cdot \text{H}_2\text{O}$
Thomsonite (<i>q.v.</i>)	$(\text{Ca}, \text{Na}_2)\text{Al}_2\text{Si}_2\text{O}_{10} \cdot 2\frac{1}{2}\text{H}_2\text{O}$

Harmotome and edingtonite contain barium; brewsterite contains some strontium; and potassium is present in phillipsite (*q.v.*). These minerals hold their water of crystallisation very loosely, and it is replaceable by a variety of substances (*e.g.* ammonia, alcohol, &c.). They lose readily with intumescence, hence the name *zeolite*, from *zein*, to boil, and *lithos*, a stone. They are readily decomposed by acids, usually with the separation of gelatinous silica; and by the action of various reagents several sub-

stitution products have been prepared. They are minerals of secondary origin, occurring usually in the steam-cavities of volcanic rocks, and have been derived from the decomposition of felspar and other alkali-bearing minerals (with which they show certain chemical analogies).

The zeolites present many points of mineralogical interest, and they afford beautifully crystallised specimens, but they are of no direct economic importance. They appear, however, to play an important part in soils by retaining in a readily soluble form the alkalis set free on the weathering of felspar. The indefinite zeolitic constituent of soils has been named *geolyte* (Ger. *Bodenzeolith*) (E. A. Wülfing, *Jahresh. Ver. Naturk. Württemberg*, 1900, 56, 35; R. Gans, *Zeolithe und ähnliche Verbindungen ihre Konstitution und Bedeutung für Technik und Landwirtschaft*, Jahrb. K. Preuss. Geol. Landesanst. Berlin, for 1905, 1906, 179-211).

On *permutite*, an artificial zeolite-like substance employed for softening water and for removing manganese and iron from water, and also used in sugar refining, and in gas-masks for absorbing gases, *v. R. Gans*, *Chem. Zentr.* 1909, i. 2031; *Chem. News*, 1919, 118, 15; also art. **WATER**. L. J. S.

ZEUNERITE *v. URANITE*.

ZIBETHONE *v. KETONES*.

ZINC. Sym. Zn. At.wt. 65.38, Richards and Roger; Baxter and Hodges. This metal was mentioned by Albertus Magnus, who died in 1280, the name then employed being 'golden marcasite.' The modern word zinc appears first in the writings of Paracelsus, about 1500, although the identification of zinc as the metal from blende is due to Homberg in 1695.

The metal had, however, been produced at a much earlier date, probably by accident. Zinc bracelets were discovered in the ruins of Cameros, destroyed circa 500 B.C. Libavins carefully examined the properties of zinc about 1595.

From the fact that the variation of the cubical expansion of zinc with temperature exhibits singular points at 176° and 320°, it is surmised by L. Losagn (Gazz. Chim. Ital. 1923, 53, 539) that this metal exists in at least three allotropic forms.

According to Egerton (*Nature*, 1922, 110, 773) it has been found possible to separate zinc by fractional distillation into a distillate and a residue, the densities of which bear to that of the initial metal the ratios 0.99971:1 and 1.00026:1, respectively, the differences being greater than the probable experimental error; see also Egerton and Lee, *Proc. Roy. Soc.* 1922, 103, 499.

Ores of zinc were known to the ancients, and were employed by them both for the manu-

facture of brass by the calamine process, and also in medicine. The working of zinc ores in Europe in modern times dates from the introduction of the use of brass, and there are records extant which show that in 1439 the Vieille Montagne calamine mines had been worked for a considerable time by the men of Aix. Metallic zinc was sometimes produced accidentally during the smelting of copper, but is stated to have been first made directly from calamine by Henckel in 1721 (Percy, Metallurgy, i. 520). A zinc factory was erected at Bristol by Champion in 1743; but the production in this country was small, the greater part of the metal required being imported from China and India, and zinc is stated to have sold in 1731 for £260 per ton, or more than eight times its present value. Other works were erected in the United Kingdom, and the demand gradually increased with the introduction of the direct method for the manufacture of brass. In England the process of distillation *per descensum* in fireclay crucibles was adopted; this has scarcely been used elsewhere, and is now completely abandoned in this country. The important zinc industry of Silesia in Germany was commenced in 1799 by Ruhberg, who had learned the process in England. The Liège (or Belgian) process was invented by Daniel Dony in 1809, and works were immediately erected for carrying out the process at Liège. These works ultimately developed into the Société de la Vieille Montagne in 1837, and this Société is now one of the largest zinc-producing companies in the world. Zinc smelting was not introduced into the United States until 1850. It was not till 1920 that the exports of zinc from England to India about equalled the total imports, and this country could be considered for the first time to supply itself with zinc. Since that time, however, the trade has fluctuated considerably, so that in 1864 the total production of zinc in the United Kingdom did not equal one half of that required in the Birmingham brass trade alone.

In recent years the world's production of zinc (or 'spelter') has steadily increased, though the industry is limited to comparatively few centres. On the continent smelting is conducted in Belgium, Westphalia, and Silesia; in America the centres are Kansas, Illinois, Oklahoma, and New Jersey; in Australasia, particularly in Tasmania; in the United Kingdom at Swansea, in Durham, and near Birmingham. The world's production of zinc in 1919 was about 520,000 tons, including 410,000 tons in the United States, but only about 20,000 tons in Great Britain, where the output was limited by shortage of ore and labour troubles. During 1919 British imports of spelter amounted to 94,226 tons.

According to the Imperial Mineral Resources Bureau, the following figures show the world's smelter production of metal for the year's covered by the publications:—

	1919	1920	1921
Zinc, long tons .	645,000	705,000	432,000

(J. Chem. Ind. 1923, 42, 966).

In 1919, 1920, and 1921, the contribution of the British Empire to the zinc production of the world was 11 p.c., 6 p.c., and 30 p.c. respectively, of the world's production, the low figure for 1920 being due primarily to the

strikes at the Broken Hill mines in Australia. In 1913 the United States consumed 308,000 tons, Germany 228,000 tons, and the United Kingdom 191,000 tons. Those three countries are the chief consumers of the metal. The British Empire meets only one-third of the requirements of the Mother Country.

The two most noticeable features in respect of zinc at the present time are: (1) The rising production of electrolytic zinc, notably in Tasmania, Canada, and the United States of America; and (2) the fact that, as a result of the war, the world's smelting capacity of zinc is largely in excess of the ore-production. The capacity in this respect of the United States alone is now 800,000 tons per annum. The electrolytic process is now an acknowledged commercial success, although still the greater part of the production is due to distillation (Redmayne, J. Soc. Arts. 1923; J. Soc. Chem. Ind. April 27, 1923).

The Derbyshire mines were once of great importance, but their output now is negligible. Between 1880 and 1910 the British production of zinc increased tenfold. At the end of the nineteenth century a very important zinc industry had grown up in Kansas. It depended largely on natural gas for fuel, and with the gradual exhaustion of the gas supply many spelter works were closed, and the industry migrated to the coalfields of Illinois or to Joplin.

Ores of zinc.—The most important ores of zinc are the sulphide and carbonate. *Zinc blende* (ZnS) is commonly called 'black jack' by the miner on account of its dead black colour and high lustre. The use of blende for the manufacture of zinc and brass was patented in 1758 by Champion of Bristol. Previously the source of the metal was the carbonate, *calamine* ($ZnCO_3$), and this was the only ore used in Belgium until about 1855, when roasting of blende was adopted. Both these ores are widely distributed and are now extensively employed. Of less importance are the oxide (which usually contains oxide of manganese, and from its colour is called red oxide of zinc), and the silicates.

In New Jersey red oxide of zinc occurs together with magnetic oxide of iron in *Franklinite* from which the zinc is first extracted, and the residue is afterwards smelted for spiegel-eisen in the blast furnace. For ores which consist largely of oxide of zinc, but with some iron, magnetic concentration is now employed, the magnetite being removed, and an ore suitable for the zinc smelter obtained. The flue dust from the blast furnace used in the manufacture of iron is also frequently sufficiently rich in zinc to render its extraction advantageous.

The greater part of the zinc smelted in the United Kingdom is now obtained from imported ores. Within the Empire are to be found some of the largest deposits of zinc ore in the world, e.g. Broken Hill, Australia, Bawdwin mines of Burma, Rhodesian Broken Hill, Tasmania, and British Columbia. Ores imported chiefly from Spain, Algeria, and Sardinia were prior to the war mostly used. Zinc ores are closely associated with those of lead, and the two metals are in many cases obtained from the same mine—just as in the case of lead. The United States of

America far exceeds any other country as producer of zinc.

Extraction of zinc.—It is necessary that the ores used for the extraction of zinc should be as rich and as uniform in character as possible. The ore as purchased by the smelter usually contains at least 50 p.c. of zinc, though 45 or even 40 p.c. ores are used if they contain other valuable materials to replace the decrease in zinc. The ores as they occur are often only poor in zinc, and require to be concentrated by washing in the case of calamine ores this is usually a simple matter, but with blendes which are frequently associated with other sulphides, concentration is a more complicated operation, though with modern appliances, careful sizing, and the necessary attention, a remarkably perfect separation can be effected. The slimes produced during concentration are again treated, 'true vanners' being now used for this purpose, and such portions as are rich in zinc are dried and smelted in mixture with other materials as afterwards described.

'Complex' ores, i.e. ores containing other metals in addition to zinc, have been the cause of considerable loss in times past, and enormous quantities of tailings were accumulated. These are now treated by flotation processes which separate the metallic sulphides from the gangue. In oil separation processes the dry, finely-crushed ore is mixed with a small quantity of oil, and is then washed with water. The metallic particles, or other bodies with smooth surfaces like sulphides, are wetted by the oil, and float upon the water, while the earthy portions sink to the bottom. In the Elmore oil vacuum process separation is assisted by the aid of partial exhaustion of a large metal receiver into which the oiled slimes and water enter. The air films surrounding the oiled particles are thus expanded and the separation much improved. In other cases diluted acid is employed, and with suitable ores gas bubbles are produced which cause the particles rich in metal to rise to the surface of the liquid. These flotation processes are now of such importance that from the Central mine at Broken Hill in Australia one-tenth of the total zinc ore of the world is obtained. The original ore contains 16.5 p.c. lead, 18.5 p.c. zinc, and 13 oz. of silver per ton. The concentrates account for 90 p.c. of the lead present, 85 p.c. of the zinc, and 88 p.c. of the silver (Sulman, Jour. Inst. Min. and Metallurgy, 1911, 47, 20).

Previous to the outbreak of war in 1914, the control of these Broken Hill concentrates was largely in German hands.

When the ores have been thus concentrated, they are calcined or roasted to convert them as completely as possible into zinc oxide. Calamine is readily calcined, and this is frequently conducted in kilns with the waste heat from the smelting furnaces. On the other hand, blende requires much care and experience in roasting, so as to prevent the formation of difficultly decomposable sulphate. Blende is generally roasted in multiple-bedded reverberatory furnaces, sometimes with the waste heat from the smelting furnaces. By the use of multiple-

roasting furnaces a considerable economy of fuel and more uniform heating are obtained. It has generally been considered that the presence of any sulphur in roasted blende leads

to loss of zinc, owing to sulphide being left in the retort, but, according to A. Voigt (J. Soc. Chem. Ind. 8, 1986), the zinc left in the retort is chiefly in the form of oxide, while the sulphur in roasted blende is in the form of sulphates of metals generally other than zinc, and the presence of a small quantity of sulphur in roasted blende does not reduce the yield of zinc.

In roasting blendes a quantity of zinc fume is produced, and may lead to a somewhat considerable loss of zinc. This fume has been utilised by Krause-Cöthen for the manufacture of zinc carbonate (Berg. u. Hütt. Zeit. 1891, 246). The blende roasted at Oberhausen contains 0.02 p.c. of mercury. The dust deposited from the roasting kilns contains about 7 p.c. of mercury, which is extracted, and the sulphur dioxide from the gases is used for the manufacture of sulphuric acid (Chem. Zeit. 10, 1039).

Great advances have been made in recent years in the furnaces used for roasting blende, the object being to economise fuel and labour, to obtain a more uniform product, and to utilise the sulphur dioxide evolved. This branch of the subject has been historically treated and fully illustrated by E. Schutz, Metallurgie, 1911, 635. One form of such furnace which has met with considerable favour is known as the Merton. It is multiple-bedded, and mechanically stirred.

After calcination the finely-divided ore is in all cases mixed with a suitable proportion of ground coal (non-caking), or other carbonaceous material, and heated to bright redness in a retort, the form and dimensions of which vary with the locality and the nature of the ore. The carbon unites with the oxygen of the ore to form carbon monoxide, and zinc is set free; the metal at the high temperature employed is converted into vapour, which is caused to pass into suitable receptacles, and condensed. The processes which are, or have been, used for the extraction of zinc differ merely in the form, arrangement, and number of the retorts, and in the methods adopted for supporting and heating them.

As the temperature at which the reaction $\text{ZnO} + \text{C} = \text{Zn} + \text{CO}$ takes place under ordinary atmospheric pressure is about 1050° , and nearly as high in a vacuum, the temperature of the retorts is necessarily high. The fuel consumption is therefore high, and the wear and tear of the retorts considerable. The difficulty of condensing the zinc vapour is increased by the fact that it is accompanied by carbon monoxide and other gases.

According to Lemaire (Compt. rend. 1920, 170, 807), zinc oxide is readily reduced directly by carbon without the necessary intermediate formation of carbon monoxide. The amount of carbon entering into the reaction is intermediate between the amounts necessary for the two possible actions $\text{ZnO} + \text{C} = \text{Zn} + \text{CO}$; $2\text{ZnO} + \text{C} = 2\text{Zn} + \text{CO}_2$. This is explained on the ground that the reduction of zinc oxide by carbon monoxide $\text{ZnO} + \text{CO} = \text{Zn} + \text{CO}_2$ takes place with a velocity greater than that of the reduction of carbon dioxide by carbon. The first reaction commences at 350° , and the second only at 400° (Chem. Soc. Abstr. 1920, ii. 313).

It is advantageous to crush the materials thoroughly, and to have as large a condensing space as possible. The condensers should be just sufficiently hot to keep the condensed metal

in the liquid state, as, if the receivers are too hot, zinc is lost by volatilisation, while if the temperature is too low a coarse crystalline product is obtained. It is necessary that the retorts should be kept filled with carbon monoxide; if carbon dioxide is present, part of the zinc is oxidised and zinc and zinc oxide distil over together. For this reason it is necessary to leave a little of the ore unreduced in the retort at the end of the process (Steger, J. Soc. Chem. Ind. 5, 607).

The following general principles have been laid down for the construction of zinc furnaces by M. F. Laur (Bull. Soc. Indust. Minérale, 1874, 3, 395; Inst. C. E. 41, 317):—

1. That it is not prudent to construct furnaces the internal capacity of which exceeds about 32·5 cubic yards.

2. The thickness of the charge to be reduced in the muffles should not exceed 7 ins., and the vessels should not exceed 20 ins. in height, or 5 ft. in length.

3. The maximum capacity which can be advantageously given to the retorts is about 22 gallons.

4. The total internal volume of the retorts should be about one-third of the volume of the furnace in which they are heated, since experience shows that about two-thirds of the space is required for supports and free circulation.

Four processes for the extraction of zinc have been actually worked on a considerable scale—namely, the English, Carinthian, Belgian, and Silesian.

1. In the *English process*, adopted by Champion at Bristol, large fire-clay crucibles were used, and the method was that known as distillation *per descensum*. The process involved the use of an excessive amount of fuel, and only a comparatively small amount of zinc could be produced. This manufacture forms a very interesting chapter in the metallurgy of zinc, and has been fully treated by Dr. Percy (Metallurgy, i. 550), but as it has been entirely superseded, will not be here described in detail.

2. The *Carinthian process*.—The process formerly adopted in Carinthia was in principle similar to the English method, the ore being charged into vertical pipes or retorts of fire-clay, and distillation being effected *per descensum*; a single furnace sometimes contained over 250 such pipes. This process is also now abandoned.

- 3 and 4. *Belgian and Silesian processes*.—The only processes now in extensive operation for the smelting of zinc are the Belgian and Silesian, neither of which is confined to the countries in which it was invented. The two systems are sometimes combined in the same furnace, the retorts in the lower or hotter part being on the Silesian principle, and in the upper part on the Belgian. In each case the retorts are of fire-clay, and are generally made on the premises. In this country they are still frequently moulded by hand, then air-dried for about a fortnight, and afterwards heated to redness in a separate furnace before being set in position. By an improvement, the invention of M. Dor, which has been largely adopted on the Continent, and to some extent in the United Kingdom, the retorts are subjected to a pressure of 3000 lbs. to the square inch during manufacture. Great care is taken in the selection of suitable clays, in

the preparation and tempering, and in pressing the retorts. They are thus made very thin, and yet possess great durability. The differences between the Belgian and Silesian systems are in the shape, size, and method of supporting the retorts, in the amount of charge used, and in the arrangement of the retorts in the furnace. In each system direct firing by coal was formerly universal and is still occasionally used, but gas-firing is now very generally employed. In Wales and in the United States regeneration by reversals, on the Siemens' principle, is generally adopted, but in Belgium continuous regeneration is preferred. In this system the gas producers are not separate from the furnace, but are placed in the furnace below the retorts. The products of combustion circulate by a zig-zag course through firebricks. The firebricks are provided with hollow channels, through which is drawn the air used for combustion. Such furnaces appear to work very satisfactorily and to require little attention or repair. The introduction of gas furnaces has led to considerable saving of fuel, which in Silesia was formerly 3·5 tons of coal per ton of ore, and is now about one-third of that quantity; gas firing has also led to the use of larger furnaces and given longer life to the retorts. The result has been that, in Silesia, while the number of works has actually decreased, the production of zinc has greatly increased (*v. M. Georgi, Zinc Industry of Upper Silesia*; Berg. u. Hütt. Zeitung, 36, 71, 78, 97; Inst. C. E. 49, 369).

The retorts used in the *Belgian process* are cylindrical or elliptical in shape, being closed at one end; these retorts are supported at the extremities, and are set in the furnace in tiers, each retort being inclined, and higher at the back than the front. The elliptical retorts are used for the lower tiers, where the temperature is highest, and they are sometimes air-cooled at the bottom. The introduction of the charge requires considerable skill. As the material is finely divided, particularly when fine concentrates are employed, it has been found advantageous to briquette the mixture by pressure, and this improvement is steadily gaining ground. Charging by electrically driven machines has also been successfully introduced. The mouths of the retorts are fitted with condensing tubes of clay in which the zinc collects, partly in the form of metal and partly in the form of more or less oxidised dust, which deposits chiefly in a sheet-iron nozzle fitted to the clay tube. The workman judges of the progress of the operation by the colour of the flame or vapours which are evolved. Brown vapours are first given off, and with these any cadmium passes over; they are succeeded by the characteristic flames of zinc, which continues until the operation is completed. The loss of zinc by the Belgian process is about 10–15 p.c. of that originally present in the ore; while in the Silesian process, in which poorer and more refractory ores are employed, the loss is 5, or even 10 p.c. greater (F. Juretzka, *Metallurgie*, 1911, viii. 1).

In the *Silesian process* the retorts are C-shaped; the width is the same as that of the Belgian retorts, but the height is greater, and as the retorts are supported in the furnace from beneath, they are made longer than in the Belgian process—consequently the charge is

greater. The retorts are usually placed in a single row in the furnace, which occasionally contains as many as forty such retorts, though about thirty-two is stated to give the best results, and a smaller number is frequently employed. At Freiberg the muffles were arranged in two rows one above the other, and each row contained sixteen muffles. In recent years the tendency has been to use a much larger number of retorts than formerly, so that the charge of ore per furnace has been raised from 15 cwt. to 8 or 10 tons.

In the lower part of the front of a Silesian muffle a hole is provided for the purpose of introducing the charge, and removing the residue after the distillation is complete. This method of charging, combined with the underneath support, gives greater durability to the Silesian muffles, so that, though in a given time the Belgian furnace may make more zinc, the annual production is rather in favour of the Silesian (*v. F. A. Thum, Notes on Zinc Smelting, Eng. and Min. Jour.* 1879, 275; *Inst. C. E.* 58, 407). The cost of calcining the ore, and smelting the zinc, in a modern works in South Wales, averaged about £3 per ton of spelter produced (1911).

The zinc works of Prince Hohenlohe in Silesia include three smelting works, with a total of 106 furnaces, and a separate calcining works for the preparation of zinc blende for distillation. The fourteen long double-bedded calcining furnaces employed have each an output of 220 lbs. of roasted ore every 5 hours. Each zinc furnace contains thirty-two muffles, heated by gas from Boetius producers. Every furnace is arranged with sixteen niches, each containing two muffles, while two furnaces are built together so as to form a double furnace. Two spaces are provided at either end of the double furnace, one for tempering the muffles, and the other for calcining the lump calamine. Most of the calamine is charged raw, as the carbon dioxide is driven off long before the temperature of reduction is reached. The charge per muffle weighs 507 lbs., and consists of a mixture of roasted blende, lump calamine, and dried slimes. The daily yield is about 108 lbs. of zinc. The zinc contains 3-4 p.c. of lead, which is reduced by refining to 1.07 p.c. The refining is conducted in a reverberatory furnace with an inclined base, in the well of which the metal collects, the lead at the bottom and the zinc above. Every 12 hours about half a ton of zinc is tapped, and the same amount of raw zinc is charged in; the lead is removed at longer intervals. An exactly similar process is used in Birmingham for refining Continental zinc previous to rolling. The refined zinc contains about 1 p.c. of lead, 0.02 p.c. of iron, and 0.04 p.c. of sulphur (*Berg. und Hütt. J.* 1889, 389; *Inst. C. E.* 101, 382).

For full particulars of modern practice in zinc smelting, especially in reference to the United States of America, W. R. Ingall's standard treatise on the Metallurgy of Zinc should be consulted. An excellent monograph by E. A. Smith, *The Zinc Industry* (Longmans, 1918), may also be read with advantage.

The demand for spelter of high chemical purity is now considerable, such metal being required for the production of the ductile brasses. One of the most remarkable advances in con-

nection with the metallurgy of zinc in recent years has been the improvement in the quality of the product when required for special purposes. Formerly 98 or 98.5 p.c. zinc was considered satisfactory, upwards of 1 p.c. of lead and a few tenths p.c. of iron being present. It is now possible to obtain regularly considerable quantities of metal guaranteed to contain over 99.75 p.c. of zinc, and upwards of 99.9 p.c. is also sold at a rather higher price. Such metal is either produced electrolytically, as afterwards mentioned, or by the use of a filter of carbon, firebrick, or other crushed and porous material placed in the mouth of the ordinary zinc retort. This filter retains the lead, while zinc vapour passes through and is condensed (*see Primrose, Production of Pure Spelter, Inst. of Metals, 1909, ii. 231; Bannister, Carbonaceous Filters in the Smelting of Zinc, Inst. of Metals, 1910, i. 213*).

Zinc of high chemical purity is also obtained by the distillation of 'hard zinc' produced in the galvanizing process (*see p. 576*). This hard zinc is an alloy of iron and zinc which is less fusible than zinc, and hence separates from the excess of zinc. Hard zinc is free from lead, and on distillation yields lead free zinc spelter.

Treatment of zinc ores in the blast furnace.—In order to reduce the consumption of fuel and labour in the extraction of zinc a number of attempts have been made to reduce zinc in the blast furnace, but hitherto without much success. The difficulty experienced is due to the fact that the vapour of zinc and the furnace gases must, in such a furnace, pass away together, and during the condensation which ensues a reaction takes place between the zinc and the carbon dioxide of the gases, thus $\text{Zn} + \text{CO}_2 = \text{ZnO} + \text{CO}$ reproducing oxide of zinc, and the ultimate result of the operation is merely to carry zinc oxide out of the blast furnace into the condensing apparatus. This action has been studied by Lencauhez (*Mém. Soc. Ingén. Civils*, 1877, 568; *Inst. C. E.* 51, 332), who found that zinc was still oxidised when the proportion of carbon dioxide was only 0.5 p.c. of the gas employed. Zinc vapour is also oxidised by any water vapour which may be present. By very rapid cooling of the gases Lencauhez succeeded in reducing the oxidation of the zinc to as little as 5 p.c., but after numerous experiments he concluded that this process is not likely to be commercially successful.

In some cases, with relatively poor complex ores containing zinc, a blast furnace smelting is adopted with the deliberate intention of volatilising the zinc as oxide. This is condensed, usually with the aid of bag filtration, and sold to the smelters to be dealt with in the ordinary way.

In 1878 Binon and Grandfils, in Stolberg, made the attempt to use a zinc oven with upright retorts. They aimed at making the Carinthian method continuous. The materials containing zinc were heated with reducing agents by gas in reduction spaces in the form of shafts, which were filled above and emptied below.

Electric smelting of zinc.—Considerable attention has been devoted to this subject during the past few years, and a lengthy list of patents has resulted. In the opinion of competent and disinterested observers the solution of the problem of the blast furnace reduction of zinc will come by means of the application of

electricity. Two typical processes may be here mentioned. In that of Snyder, adopted in British Columbia, complex ores are calcined to oxides, mixed with fluxes to give a slag melting at about 1050°, and treated in an electric furnace. The current passes through the molten slag, under which the lead is collected in a well. The zinc is volatilised and condensed in suitable chambers. The De Laval process, worked in Sweden, is conducted in an arc furnace into which the roasted ores are charged after mixing with flux and coal. The product is a coarse metal containing zinc, lead, and other impurities. This coarse metal is refined by distillation in another furnace, and zinc of high purity is obtained, together with zinc dust or fume and base lead bullion. One h.p. year is claimed to produce 800–1000 k. of metallic zinc, much of which is, however, in the form of dust. The current cost is about half the total charges. The electric processes depend for their success upon electricity from cheap water power, and are not likely seriously to compete with the old-established reduction centres, at all events for some time to come (*see* Sulman, J. Inst. Min. and Met. 1911, lxi.; Min. Mag. 1911, 310, 389).

Wet methods of extracting zinc.—One of the most difficult problems connected with the metallurgy of zinc is that of the treatment of complex ores. These may contain, in the aggregate, very considerable proportions of metallic constituents, but in that a number of metals are present together the ores cannot be treated by ordinary methods. Such ores usually contain about 12–28 p.c. of zinc, and 5–15 p.c. of lead, together with a few p.c. of copper, some ounces of silver per ton, and frequently small proportions of other constituents. Such ores are now frequently treated by oil vacuum or other concentration processes so as to classify the metalliferous portions into separate saleable products whenever possible. Various wet methods of extraction, usually connected with electro-deposition, have from time to time been suggested, and have been worked on a more or less considerable scale, though till recently without much commercial success. It was only after many trials that copper-refining by electro-deposition became a commercial success; and yet copper is worth more than double the price of zinc. The electro-motive force required for the deposition of copper is less than that necessary for zinc, and the strength of current that may be used with copper is greater. Thus electrolytic methods of extraction of zinc have to contend with the disadvantages of the comparatively low intrinsic value of the metal, and of comparatively slow deposition.

Where electro-deposition is employed, there are two methods open for extracting the zinc; in the first the ore itself may be used as anode; or, secondly, the ore may be roasted or treated with solvents to convert the zinc into a soluble form.

1. Luckow proposed to mix the ore with coke in order to render it a conductor, and to place it in an open chest in an electrolyte consisting of a somewhat strong and acid solution of common salt or zinc chloride (20–30 p.c. Zn). The metal was deposited either upon a zinc plate or upon a cathode of coke, (*Eng. Pat.* 9158, 1886) proposed a

method, but used magnesium chloride as electrolyte, and adopted special arrangements for collecting the evolved chlorine.

2. Many processes have been proposed for rendering the zinc in complex ores soluble, and in a number of these it is proposed to recover the zinc from solution by electro-deposition.

Lambotte and Doucet proposed to roast blende to oxide, dissolve in crude hydrochloric acid, precipitate the iron with chloride of lime and zinc oxide, and electrolyse the solution.

Parnell calcined complex ores to oxide, dissolved in dilute sulphuric acid, which was obtained as a by-product, precipitated the copper by metallic iron, and evaporated the liquor to a mud. Zinc sulphide was then added, and zinc oxide produced by heating the mixture strongly. The zinc oxide so obtained was sold to the smelters. Maxwell Lyte calcined the ore, and dissolved in hot dilute hydrochloric acid; the lead was allowed to separate as chloride on cooling, the iron precipitated by limestone, the copper with scrap iron, and the zinc as oxide by lime. Létrange was one of the earliest workers in the direction of electro-deposition of zinc; in his process blende was carefully roasted at low temperatures to produce zinc sulphate, which was dissolved with hot water and dilute sulphuric acid. The solution was then electrolysed, using an anode of lead (or carbon) and a cathode of zinc. The current used must have a high electro-motive force owing to the peroxidation of the surface of the lead.

Among other suggestions the following are worthy of notice. In 1886 Lea and Hammond (*Eng. Pat.* 10868) suggested the use of hydrochloric acid as a solvent for roasted ores previous to electro-deposition, while in the same year Squire and Currie (*Eng. Pats.* 12249 and 12630) proposed the use of an alkaline solution for the same purpose, and in 1887 Watt patented (*Eng. Pat.* 6294) the application of dilute vegetable acids for a similar object. Again, Burghardt (*Eng. Pats.* 8986 and 13182, 1888; 659, 1889) proposed the use of an alkaline solution made by adding the roasted ore, previously mixed with 3–7 p.c. of powdered coal or charcoal, to melted caustic potash or soda. The mass was extracted with water, the zinc electro-deposited, and the alkali recovered to be used over again. Croselmire (*Eng. Pat.* 4286, 1888) proposed to mix the ground ore with clay, and form into perforated pressed bricks which are roasted into sulphate in kilns. The roasted mass is extracted with hot water and an equivalent of dilute sulphuric acid, air is blown through the liquors to precipitate iron and manganese, and, after settling, the clear liquor is electrolysed, or the zinc may be precipitated by soda ash. In 1889, also, Cunningham (*Eng. Pat.* 9987) again patented the use of an alkaline solution obtained by fusion with caustic soda.

Among methods of another class proposed for the treatment of complex zinc ores may be mentioned that of Perino (*Eng. Pat.* 10657, 1888) who fused the blende in clay retorts at 150°–200° with ferric nitrate in the proportion of about 5 parts of nitrate of iron to 1 of zinc. The mass was extracted with water and a solution of zinc sulphate obtained. Arrangements were made for recovering the ferric nitrate, Siemens and Halske also (*Eng. Pat.* 3533,

1889) used ferric sulphate for extracting zinc from complex ores, while Seagall (Eng. Pat. 4871, 1889) employed a slightly acidified solution of ferric chloride for the same purpose.

The complex ores of Leadville, U.S.A., containing 25 p.c. zinc, 15 p.c. lead, 20 p.c. iron, are roasted to sulphate, extracted with water; the residue chlorinised to complete the extraction of the zinc, and the zinc precipitated from the solutions as oxide (J. Soc. Chem. Ind. 7, 572).

A process for the electrolytic production of zinc which was formerly conducted on a considerable scale in the United Kingdom is a modification of the Höpfer patent, introduced at Northwich by Messrs. Brunner, Mond, Ltd. The primary object is the production of chlorine from the calcium chloride liquors made in the ammonia-soda alkali process. These liquors are treated with zinc oxide (roasted zinc ores) and carbon dioxide, when calcium carbonate is produced and zinc chloride liquors obtained. This solution, after the removal of all the more electro-negative elements, is electrolysed, a current density of as much as 30 amperes per sq. ft. of cathode surface being allowable. The products are zinc and chlorine. The cathode consists of a series of discs of iron which revolve on a horizontal axis; the anodes are of carbon and are enclosed in wooden frames, the sides of which are enclosed with cloth diaphragms. The chlorine evolved is subsequently converted into bleaching powder. The zinc is stripped off the cathode plates, remelted, and cast into ingots. The great difficulty is to obtain a smooth adherent coating of zinc, and to prevent, as far as possible, the formation of spongy zinc. The exact nature of the latter product, and the cause of its formation, are still not thoroughly understood. More recently electrolytic zinc has been manufactured by Messrs. Chance and Hunt of Oldbury. It is understood that the method employed is similar in principle to that above described, though the details are kept secret. The zinc obtained is sold with a guaranteed purity of 99.96 p.c., which makes it of great value in the production of ductile brasses, and for other purposes where the presence of lead, &c. would be detrimental.

To avoid the necessity for electrolysis of the zinc solutions obtained from complex ores, processes have been introduced to precipitate the zinc in a form suitable for sale to the zinc smelter. A typical process is that in which sulphur dioxide, obtained from blende roasting, is used to extract zinc from roasted ores. With excess of sulphur dioxide the zinc passes into solution as bisulphite, and is separated from the residues. These contain lead, silver, &c., and are sold to the smelters. By the removal of half the sulphur dioxide from the solution insoluble zinc sulphite is thrown down. This sulphite is filtered off, dried, and calcined in a muffle at a low temperature. Zinc oxide is obtained in a form suitable for spelter production, and the sulphur dioxide is added to the calciner gases to enrich them for fresh leaching operations (Eng. Pat. 21759, 1908).

The foregoing process, after having been used for several years by one important British company, was replaced by a method which included roasting with partial sulphating of the zinc, extraction with dilute sulphuric acid,

precipitation of the iron and soluble silica by lime, and of the copper and cadmium by zinc. The solution was then electrolysed, and the sulphuric acid liquor used over again. For electrolysis the solution must not be too strong or too weak; in the latter case the resistance is unduly high. During the electrolysis of zinc sulphate zinc crystals are deposited in directions normal to the cathode surface. A peculiar ring structure is exhibited by sections parallel to the latter. Electro-deposition occurs most readily at angles, corners, and rough parts of the cathode.

The largest electrolytic zinc works in the British Empire is situated at Risdon, near Hobart, in Tasmania. It has a paid-up capital of upwards of £2,000,000, and was erected 1921 to treat Broken Hill concentrates as Tasmanian ores from the Mount Read and Rosebery mines. The former assay 47 p.c. zinc, 30 p.c. sulphur, 7 p.c. lead, and 10 oz. of silver per ton. The latter average 27 p.c. zinc, 7.3 p.c. lead, 9.5 oz. silver, and 2.5 dwts. gold per ton. The ores are roasted in multi-bedded mechanically rabbled calciners, the oxide of zinc extracted by dilute sulphuric acid, and the solution purified from iron and silica by addition of lime. The clear liquid is deprived of cadmium and copper by addition of zinc dust, and the purified zinc sulphate electrolysed. The lead-rich residue is dried and sold to smelters for the extraction of lead, silver, and gold. The cadmium is recovered, and is now one of the chief sources of the world's supply of that metal. The current available is 30,000 h.p.; it is supplied at a cheap rate, by the Tasmanian Government, at 11,000 volts a.c., the greater part of which is transformed to d.c. at 550 volts and delivered into the cell room. About 800 tons of zinc cathode sheets are produced weekly; they are melted and cast in slabs of about 50 lbs. weight, which contain 99.95 p.c. zinc. The British Government has undertaken to purchase a quantity not exceeding 45,000 tons per annum for a period of years.

The brittleness of electrolytic zinc is probably due to the presence of hydrogen, which in the case of the sample investigated was found to be present to the extent of 0.55 p.c. When electrolytic zinc is melted the hydrogen flame can be observed. When heated to 105°–110°C. for some hours a loss of weight of 0.025–0.04 p.c. occurs. A plate of zinc so treated becomes curved slightly, and a considerable volume of hydrogen is evolved. When heated to a temperature above 180°C. the plate becomes very curved, the concavity being directed towards the original cathode surface. The phenomenon is accompanied by a decrease of 0.7 in the value of the density of the metal. The electrical conductivity of electrolytic zinc is practically the same as that of pure zinc, but the value at 195°C. is much below the anticipated value. This decrease and the decrease of density occurring at about the same temperature are not reversible phenomena, but are connected with the evolution of hydrogen. Determinations of hardness at high temperatures are in agreement with the customary values. Very little, if any, hydrogen is dissolved in electrolytic zinc or electrolytic iron which has been stored for a long period (M. von Schwab,

Zeitsch. Elektrochem. 1923, 29, 188; J. Soc. Chem. Ind. 1923, 42, 607 A).

Properties.—Zinc is a bluish-white metal, which at ordinary temperatures is brittle, and when pure exhibits a beautifully crystalline fracture. Large crystals are often found in zinc rods which have been worked mechanically. The presence of impurities usually renders the fracture closer in the grain and less brilliant. Zinc melts at 419.4° , and boils at 930° . It can, however, be readily distilled in glass vessels in a vacuum, under atmospheric pressure. The vapour pressure of molten zinc up to 2 atm. is represented by

$$\log p = -66.55/T - 1.147 \log T + 12.046$$

Both zinc and cadmium have a constant atomic heat over the range of temperature from the melting-point to the boiling-point. The values are 7.5 (cadmium), 7.24 (zinc) (Braune, *Zeitsch. anorg. Chem.* 1920, 111, 109; cf. Nair and Turner, *Chem. Soc. Trans.* 1913, 103, 1534; Rodebush and Dixon, *J. Amer. Chem. Soc.* 1925, 47, 1036). Zinc undergoes two marked changes in electric conductivity, one at 170° , and the second at 340° . It is, therefore believed by Benedicks to exist in three allotropic modifications (Metallurgie, 1910, 7, 531). From observations of electrical resistance, thermal E.M.F., electrolytic potential, specific gravity, hardness, mechanical properties, thermal curves, and microstructure of the pure metal (99.97 p.c. Zn), Bingham (*Inst. of Metals J.* 24, 333) also concludes that zinc exists in three allotropic forms, the transformation temperatures being approximately 180° and 310° (cf. Laschtschenko, *J. Russ. Phys. Chem. Soc.* 1913, 45, 552; Werner, *Zeitsch. anorg. Chem.* 1913, 83, 275; Cohen and Helderman, *Proc. K. Akad. Wetensch. Amsterdam*, 1913, 16, 505; Le Chatelier, *Compt. rend.* 1890, 414, 454; Benedicks and Arpi, *Zeitsch. anorg. Chem.* 1914, 88, 237; Lorenz and Plumbridge, *ibid.* 1913, 83, 228; Janecke, *ibid.* 1915, 90, 313). According to measurements of various kinds of zinc, it exhibits two singular points, at 174°C. and 322°C. , the former corresponding with the transformation of the α to the β modification, and the latter that of the β to the γ modification. If traces of iron or tin occur in the zinc, the lower transformation point disappears, whilst the presence of cadmium causes the two transformation points to approach (L. Losana, *Gazz. chim. ital.* 1923, 53, 539-545; *J. Soc. Chem. Ind.* 42, 1923, 1075 A). Its tensile strength varies greatly according to the mode of preparation; cast zinc has a tenacity of only 1.2 tons per square inch, whilst an annealed rod gave a tenacity of 7.9 tons per square inch, and zinc wire 10 tons per square inch. Its hardness is intermediate between that of tin and copper, being equal to 6 on Turner's Sclerometer and $2\frac{1}{2}$ on Mohs' scale. Pure zinc has a density of 7.1400 at 16.3° (Egerton and Lee). The coefficient of expansion between 100° and 300° Abs. has been measured by Borelius and Johansson (*Ann. Physik.* 1924 iv, 75, 23).

Two sets of distillations of pure zinc were carried out in high vacuum under conditions to obtain a slightly different concentration of the isotopes in the final residue of the last distillate. For the determination of densities,

the metal was cast in a vacuum and seeded with about 1 mg. of a particular kind of zinc. The first set of distillations gave a residue of slightly increased density, but the distillate was of the same density as the original zinc. The second set of distillations, carried out under improved conditions, yielded a residue of increased density (about 1 part in 3700 parts), and a distillate of decreased density (about 1 part in 3600 parts). The density of ordinary zinc at 16.3° , determined from seven samples of the metal prepared as described, was found to be 7.1400 ± 0.0006 . The possibility of attributing the difference of densities to flaws, allotropes, different physical conditions, and impurities is discussed and shown to be improbable. The degree of separation obtained agrees with Dempster's observations of isotopes of weights 64-70, but is less than half what might be found for equal parts of an isotope of mass 64, and of isotopes 66, 68, and 70 (A. C. Egerton and W. B. Lee, *Proc. Roy. Soc.* 1923, [A] 103, 499; *Chem. Soc. Abstracts*, July, 1923, 490).

Though zinc is brittle at ordinary temperatures, and so tender above 200° that it can readily be crushed to powder, it can be rolled into sheet or drawn into wire at an intermediate temperature of about 100° - 150° . It is a remarkable fact that the metal when so treated retains its malleability in the cold. Zinc was first rolled early in the present century in Birmingham, and rolled zinc now forms one of the most important varieties of the commercial metal, the greater part of the zinc produced in Europe being used for this purpose. Commercial zinc always contains more or less lead and iron, together with traces of cadmium, arsenic, and sulphur, the lead being volatilised with the zinc in the process of manufacture. Kosmann has also found comparatively large quantities of thallium in commercial zinc (*Chem. Zeit.* 10, 762). The chief technical methods for the assay of zinc have been described and discussed in connection with a paper by Greenwood and Briske (*Inst. of Metals*, 1909, 2, 249). The presence of lead, which is objectionable in zinc to be used for the manufacture of the best qualities of strong brass, is an advantage in zinc that is to be rolled. For the influence of foreign metals on the rolling of zinc, see Post and Van de Casteele, *Bull. Soc. chim. Belg.* 1913, 27, 175. Ingall has studied the effect of annealing rolled zinc, and shows that sheets are stronger across the direction of rolling than with the grain (*Inst. Metals J.* 26, 281). As English zinc is relatively free from lead, it is usual to employ this variety for the production of alloys in which lead would be objectionable, while Continental zinc is imported for rolling. If the state of the market renders it advantageous to roll English zinc, this can be improved by the addition of a small proportion of lead. In addition to what is made here, more than 20,000 tons of sheet zinc is annually imported into the United Kingdom. The density of zinc varies from 6.8 to about 7.2, according to the mode of preparation. The change of density of melted zinc with temperature may be represented by the formula

$$d = 6.59 - 0.00097(t - 419)$$

When heated in the air much above its melting-point, zinc readily burns with a brilliant

greenish-white flame, producing the oxide (ZnO) which condenses in a bulky flocculent condition formerly known as 'philosopher's wool.' The white fume produced when casting brass or other zinc alloys that melt at a tolerably high temperature consists of zinc oxide. Though zinc is readily volatile, the oxide is fixed at all ordinary furnace temperatures. For remarks on the toxicity of zinc vapour, see Drinker, *J. Ind. Hyg.* 1922, 4, 177. Zinc is not affected by dry air at ordinary temperatures, but tarnishes superficially in moist air. The metal is also not attacked by mineral lubricating oils, and of ordinary animal oils it is attacked most by sperm oil and least by lard oil (Redwood, *J. Soc. Chem. Ind.* 5, 362). Zinc, both pure and commercial, dissolves readily in alkalis. Pure zinc is unattacked by water at boiling-point, and is almost unaffected by ordinary acids either diluted or strong. Commercial zinc, on the other hand, decomposes boiling water with the evolution of hydrogen, and is readily attacked by diluted sulphuric acid and by hydrochloric acid either diluted or strong. Impure zinc when amalgamated resists the action of acids exactly like pure zinc, and hence the zinc plates used in electric batteries are amalgamated so as to prevent the loss due to 'local action.'

For heat of solution of zinc in hydrochloric acid, see Richards and Thorvaldson (*J. Amer. Chem. Soc.* 1922, 44, 1051). The influence of impurities on the solubility of zinc in acids has been studied by Vandraček and Izák-Křižko (*Rec. trav. chim.* 1925, 44, 376).

This difference in the behaviour of pure and impure zinc towards acids has attracted much attention from chemists since the fact was first pointed out by A. de la Rive in 1830. Among the more important observations on the subject are those of Pullinger (*Chem. Soc. Trans.* 57, 815), Weeren (*Ber.* 24, 1785), and Centnerszwer and Sachs (*Zeitsch. physikal. Chem.* 1914, 87, 692).

Pullinger's conclusions are as follows:—Pure zinc with a perfectly smooth surface is not acted upon by dilute sulphuric acid that has been previously well boiled; pure zinc with a rough surface is readily acted upon, but less by acids that have been boiled than by those which have not. The presence of oxidising agents such as nitric acid, hydrogen peroxide, or electrolysed sulphuric acid, increases the rate of dissolution, while a reducing agent, such as hydriodic acid, almost entirely prevents dissolution; but reducing agents containing sulphur, such as sulphur dioxide, are without effect. It is not improbable that when zinc with a rough surface dissolves in dilute sulphuric acid the cause of dissolution is persulphuric acid, which acts catalytically, and in all probability pure dilute sulphuric acid would be without action upon metallic zinc, whether the surface of the latter be rough or smooth.

The solubility of impure zinc in diluted acids has been generally explained on the supposition that local electric currents are set up owing to the presence of the impurities, whilst with pure zinc no such currents are produced. Weeren, however, shows (*loc. cit.*) that the insolubility of pure zinc is due simply to the formation of a layer of condensed hydrogen on the surface of the metal, and thus the further action of the acid is stopped. Oxidising agents remove this

film and assist dissolution; in impure zinc the hydrogen, obeying ordinary electrical laws, is evolved from the surface of the impurities. The fact that dissolution is much promoted by simply brushing the surface of the metal, or by allowing the action to take place in a vacuum, appears to afford strong support of this view, which is also quite in harmony with the fact that pure zinc dissolves much more rapidly in boiling dilute sulphuric acid, when the ebullition of the liquid removes any hydrogen from the surface of the metal, than at 98° where no ebullition occurs. Pure zinc with a rough surface, as Pullinger has shown, dissolves much more readily in diluted sulphuric acid than the same metal when the surface is perfectly smooth. Weeren suggests from the above facts that the difference in the action of diluted sulphuric acid on pure and impure zinc is capable of a simple mechanical explanation.

Centnerszwer and Sachs made experiments with (1) polished zinc, (2) etched zinc, (3) rolled zinc, (4) slowly cooled zinc, (5) rapidly cooled zinc, and zinc which had been kept at 400° for eight days. Zinc slowly increases its rate of solution in a given acid to a maximum, after which the rate slowly falls off in accordance with the law of Boguski, $dx/dt = kF(c-x)$ in which dx/dt is the velocity, F the surface exposed to the acid, c the concentration of the acid, x the amount dissolved at time t , and k the velocity constant. The solution of the zinc passes through an induction period. Zinc which has been etched in hydrochloric acid dissolves more rapidly than unetched zinc. Zinc which has reached its maximum velocity of solution in 2N-hydrochloric acid, on removal from the acid and immersion in fresh acid, immediately begins to dissolve with the maximum velocity, and the rate of solution then falls off in accordance with Boguski's law. In acids of equal hydrogen-ion concentration, sulphuric acid dissolves zinc more slowly than hydrochloric acid. Specimens of zinc from the same rod show different solution-velocities, which is to be explained by the different crystal habitat. Plates of rolled zinc, on the other hand, give velocities which are uniform. Zinc which has been rubbed with emery paper dissolves much more quickly than polished zinc, and the finer the emery the more rapid the rate of solution. Zinc plates which have been immersed in iodine solution dissolve more readily than fresh zinc. The velocity of solution of zinc in acids of different concentration increases more rapidly than the concentration of the acid. A mixing of the solution increases the rate of solution. A black deposit is formed on the surface of the zinc during solution; this accelerates the rate of solution, and when it is mechanically removed the velocity decreases. Zinc which has passed through the induction period of solution retains its activity when allowed to remain in water, but loses it if kept in the air and allowed to dry. Rapidly cooled zinc has a longer induction period than slowly cooled zinc, but after the surface has been etched, both dissolve at the same rate. When slowly cooled zinc is heated to 400° for prolonged periods its induction period is increased (*Chem. Soc. Abstracts*, 1914, ii, 550; also Centnerszwer and Drukar, *J. Russ. Phys. Chem. Soc.* 1915, 47, 439; *Chem. Soc.*

Abstr. 1915, ii. 562.) For the hydrogen over-voltage of zinc, see G. M. Westrip (Chem. Soc. Trans. 1924, 125, 1112).

The question of the corrosion of zinc sheet and pipes, and of articles coated with zinc, when in use, is of great commercial importance. In dry pure air, as for instance in parts far removed from manufactories and towns, zinc roofing, when properly attached, lasts almost indefinitely with only a surface oxidation. But in the neighbourhood of towns, and especially in the vicinity of chemical manufactories, commercial zinc is rapidly corroded and spoiled. The presence of the slightest trace of free sulphuric or hydrochloric acid in the drainage water is very prejudicial. The presence of copper in any form in contact with zinc should also be carefully avoided. Thus Müller has shown (Dingl. poly. J. 269, 280) that the zinc pipes which carried the drainage water from the copper dome of the royal castle at Brunswick were rapidly attacked and corroded, while similar pipes on the opposite side of the same building were unaffected. The explanation of this difference probably was that in the presence of ammonia or of acids in the atmosphere some copper was dissolved by the rain water, and this copper being afterwards deposited on the surface of the zinc, set up an electric action resulting in the destruction of the pipes.

The presence of lead, cadmium, or iron causes an increase in corrosion by acidic agents. Minute traces of arsenic, antimony, copper, or tin can considerably increase the tendency of zinc to corrode, and this influence is particularly marked in the cases of arsenic and antimony.

G. Ducker (Zeitsch. Elektrochem, 1923, 29, 412-415) placed test pieces of pure zinc, commercial zinc, and specially prepared alloys in a bath of sal-ammoniac and determined the loss in weight. Traces of iron in the zinc or the solution produced serious effects owing to electrolytic action. The effect of cadmium is due to its influence on the structure of the metal. The effect of lead, which is a minimum at concentrations of about 1 p.c., is partly electrochemical and partly due to its influence on the structure of the metal. This is confirmed by the fact that any treatment of the metal which tends to alter the structure will increase the rate of attack. Small impurities in the sal-ammoniac increase the corrosion, especially in strong solutions, with the pure salt solutions, the attack is slowest with the stronger concentrations, which is probably due to the protective action of the reaction products. The author advocates the use of sal-ammoniac free from iron, and re-distilled zinc in the preparation of primary cells (Sci. Abstr. 1924, 27, 238). To determine the relative corrosion of zinc and lead in solutions of inorganic salts, the metal plates were suspended in salt solutions of high concentrations, and the corrosion was expressed as percentage loss of weight, the loss of weight from similar plates suspended in distilled water being taken as 100. With zinc plates, the rate of corrosion rapidly reached a maximum with increasing concentration, beyond which the rate of corrosion steadily decreased. Sulphates and chlorides gave similar results, the former producing a more pronounced decrease the critical concentration. Nitrates,

however, caused a rapid decrease in the corrosion rate throughout. The conditions influencing corrosion are the chemical action of the dissolved salt on the metal, the solubility of oxygen in the solution, the rate of solution of oxygen by the quiescent salt solution, and the physical and chemical action of the products of corrosion (J. N. Friend and J. S. Tidmus, Inst. Metals, Mar. 1924; J. Soc. Chem. Ind. 1924, 43, B. 337).

The use of galvanised iron tanks for water-cisterns has led to much controversy, particularly in the colonies, as to the effect of such storage on the health of persons who drink the water so stored. According to Bunte, the use of zinc-coated iron water-pipes is not deleterious to health, and this view is supported by Dr. Ehmann, late director of the water supply of Württemberg, and by Dr. Boardman, of Boston (J. Soc. Chem. Ind. 6, 557). But a strong feeling exists to the contrary, and, after careful inquiry, the use of galvanised tanks for drinking-water was condemned in the British and French Navies. From the well-known properties of zinc it might be anticipated that some waters, which are either slightly acid or alkaline, would attack zinc vessels, while other waters might be almost without action. The presence of chlorides would probably also be prejudicial. It is not unlikely, therefore, that the differences in the action of water on zinc cisterns, as noticed by various observers, is due in great measure to the character of the water. It is, however, certain that zinc or galvanised vessels should not be employed with acid waters.

Experiments have been conducted to determine the degree to which ordinary galvanised iron buckets are corroded by tap water, distilled water, carbonated water, milk, orangeade, and lemonade. Quantities of 1 gallon of each of these liquids (1 quart of milk) were placed in buckets and samples analysed for zinc at the end of 17 and 41 hours. The orangeade and lemonade contained the juice of twelve oranges and twelve lemons respectively and 1 lb. of sugar to each gallon. The number of mg. of zinc per litre found in the five liquids after the periods named were: tap water, 5, 21; distilled water, 9, 27; carbonated water, 193, 181; milk, 438, 1054; orangeade, 530, 854; lemonade, 1411, 2,700. The hydrogen ion concentration and titratable acidity, with phenolphthalein as indicator, were also determined in the solutions. The quantity of zinc found after 17 hours increases directly with the hydrogen ion concentration and titratable acidity. The buckets which had contained the milk, orangeade, and lemonade were visibly corroded, especially in the last-named case (J. W. Sale and C. H. Badger, Ind. Eng. Chem. 1924, 16, 164; J. Soc. Chem. Ind. 1924, 43, B. 273).

Zinc-dust is employed somewhat largely as a reducing agent, as a precipitant for gold in the cyanide process for the extraction of gold from gold ores, and in the manufacture of fireworks. It is obtained, mixed with more or less oxide, in the distillation of the metal, or can be produced by crushing the metal in a mortar at a temperature somewhat below its melting-point.

In castings zinc takes a very sharp impression of the mould, and, as it melts at a low

temperature, it has been used to a considerable extent, especially in France, for the production of statuettes and other objects of beauty, which are afterwards usually coloured or bronzed. Some of these bronzes contain about 17 p.c. of copper; this alloy expands in the mould, and gives very sharp and clear impressions (see Turner and Murray, *Inst. of Metals*, 1909, ii. 115). The introduction of photo-engraving has also in recent years led to the use of considerable quantities of sheet zinc of special quality.

Galvanising.—An important application of zinc, known as galvanising, was patented by Crawfurd in 1837. The object of the process is to coat the surface of iron with a thin layer of zinc, which protects the metal underneath from oxidation. In this respect zinc acts more perfectly than tin, which is negative to iron; in the case of tin plates the protection only lasts so long as the surface of the iron is covered with tin, but as soon as any portion of the iron is exposed to the action of the atmosphere oxidation proceeds more rapidly than in the absence of tin. Zinc, on the contrary, is more positive than iron, and thus, even though the coating of zinc may be removed in places, the protection continues so long as any zinc remains. Galvanised iron, however, cannot be used in contact with acids or alkalis, nor for the canning of fruits, meat, &c., on account of the action of vegetable acids and animal juices on the surface of the zinc.

A micro-section through a piece of galvanised iron indicates that between the iron and the zinc there is at least one layer of intermediate compound of iron and zinc (see p. 579). It is probable that the excellent wearing qualities of galvanised iron depend to a considerable extent upon the presence of this hard crystalline layer.

According to H. Bablik (*Stahl. u. Eisen*, 1924, 44, 223), the zinc coating obtained in the usual process of galvanising consists essentially of three layers—an extremely thin cementing layer very rich in iron, a slightly thicker layer of FeZn_2 and FeZn_7 , and a thicker layer of pure zinc. The lower layers are very hard and brittle and tend to make the coating crack on bending. In the new process the formation of the intermediate layers is prevented and a pliable coating is obtained, whilst economies are effected in the amount of fluxes used, and in the proportion of zinc lost in ashes and hard zinc. The apparatus consists of a cast-iron vessel having a cylindrical fireclay collar; the vessel is filled with soft lead on which a thin layer (3-6 cm. thick) of zinc floats so as to come in contact solely with the fireclay collar. A smaller fireclay cylinder dips through the zinc layer into the lead and is filled with a flux containing ammonium chloride. The articles to be galvanised are pickled in hot dilute sulphuric acid immediately before being passed through the flux layer into the lead, then up through the zinc layer. The resulting coating has a duller colour and is more coarsely crystalline than usual, but the size of the crystals can be reduced and the colour greatly improved by adding 1-2 p.c. Al to the zinc before use. The aluminium also retards the formation of oxide crusts and of hard zinc. Figures show the production of sheets together with the consumption

of zinc and lead during a year's working of the process (*J. Soc. Chem. Ind.* 1924, 43, B. 299).

The operation of galvanising is not in any way an electric process, as might be inferred from its name, but is simply a method of coating clean iron with zinc by immersion in a molten bath of the latter metal. Numerous patents have been obtained for suggested improvements in galvanising since Crawfurd introduced the process, particularly by Mallet and Morewood, but the old process is still almost universally adopted with a few improvements in details for saving of labour and the production of a better surface with a smaller consumption of zinc. Galvanising is conducted largely in the United Kingdom, and particularly in the neighbourhood of Birmingham and Wolverhampton, and in South Wales.

The iron or steel which is to be galvanised is received in the black state, coated with scale from the process of manufacture. Sheets are close annealed (i.e. annealed in large iron boxes, while carefully protected from access of air) to render them soft, but many other articles are treated without annealing. The scale is next removed by pickling in hydrochloric acid, which is used cold, or nearly cold, and which is contained in stone troughs. Tanks built of blue brick, set with sulphur joints, are also frequently used for containing the pickling acid. The strength of the acid depends on the character of the work; for wire 12 p.c. of real HCl is sufficient; for tubes, buckets, and general work an intermediate strength is best; while for sheets about 20 p.c. is generally used, and sometimes the undiluted muriatic acid of commerce (26-30 p.c.) is employed. By this method of working, pickling is usually complete in a few minutes; but on the Continent, where acid is dearer and economy is necessary, a dilute pickle is used, the water is heated, and the sheets are allowed to remain in the pickle for about 2 hours. The scale having been thus dissolved or loosened, the iron is washed with water, and, if necessary, rubbed with sand to complete the cleansing. The molten zinc is contained in a wrought-iron pot, the dimensions of which vary according to the character of the work to be done, and which is heated by means of a slow coke fire around the sides and under the bottom of the pot. The surface of the zinc is covered with powdered sal-ammoniac, which acts as a flux, and when best sheets are being treated it is usual to add about 2 or 3 p.c. of tin to the bath so as to assist in the production of a crystalline appearance of 'spangle' on the surface. In other cases remelted zinc, i.e. zinc containing some tin and lead solder, is added to the bath for the same purpose.

According to Hannab and Ithead, tin alone does not produce 'spangle' when added to the zinc bath. The action is much facilitated by the presence of lead or bismuth (*J. Inst. Metals*, 30, p. 79). In galvanising sheets also it is usual to have a pair of rolls in the bath to guide the sheet in its passage through the zinc and to improve the surface. The consumption of zinc can be somewhat reduced, and the surface considerably improved, by the use of rolls or wire brushes as the sheet leaves the bath. Koffler and Breden (*Eng. Pat.* 12485, 1885; and 18674, 1888) have patented the use of wire brushes for

this purpose; whilst Heathfield (Eng. Pat. 10089, 1886; and 1682, 1890) has introduced brushes which press evenly on the surface of the sheet, as it leaves the bath, and he also adds fine wire brushes, together with improved rolls for feeding in the sheets. Corrugated sheets form a considerable portion of the trade; these are galvanised plain, and afterwards passed through corrugating machines in the cold. In galvanising wire, it is reeled through the pickle trough and the zinc-bath continuously, while netting is woven in the black, and afterwards reeled like wire. A continuous arrangement for this purpose has been patented by Vibart (Eng. Pat. 14297, 1889). The proportion of zinc taken up by the iron in galvanising varies considerably, being as high as 25 p.c. with moderately small wire, and less than one-fourth of this with many articles such as anchors, chains, and large elbows. In some galvanising works the sheets are pickled with hot diluted sulphuric acid, and the molten zinc is covered with zinc chloride instead of ammonium chloride; but the process above described is in much more general use.

The molten zinc gradually takes up iron during the galvanising process, and forms an alloy which is heavier than zinc, and which sinks to the bottom of the bath. This is removed from time to time and cast in plates, which, when broken, exhibit a close-grained fracture with black spots. This alloy is known as 'hard zinc,' and contains from about 2 to 5 p.c. of metallic iron. It is usually re-melted at a higher temperature, when it separates into two portions, one being tolerably pure zinc. The other portion is much less fusible, and forms a crystalline or granular material of the colour of zinc; it is very friable, and frequently exhibits surface colorations of great beauty. In this form it is generally sold to the smelter, and contains about 7.5 p.c. of iron, corresponding to FeZn_{10} , though exceptionally compounds are produced which contain upwards of 25 p.c. of iron (cf. Taboury, *Compt. rend.* 1914, 159, 241; Le Chatelier *ibid.* 1914, 159, 356).

The ammonium chloride used as a flux in galvanising is gradually lost during the process, and fresh additions have to be made as required. This loss is doubtless due in part to volatilisation of the salt itself, but also to a reaction which takes place, whereby zinc chloride is formed and ammonia set free. It has been proposed to collect the fume of ammonium compounds evolved from the galvanising bath by suitable exhausting arrangements and scrubbers in which the gases are washed by diluted acid, and it is stated that such an arrangement not only very much improves the atmosphere of the manufactory, but actually yields a profit in working.

The result of the action of the ammonium chloride and of atmospheric oxygen on the molten zinc during galvanising is the production of a scum which is known as 'flux skimmings,' and which is removed from time to time. This material consists of chloride and oxide of zinc, together with some ammonium chloride and dirt; it is usually sold to the smelters. Heathfield (Eng. Pat. 14411, 1885) proposed to dissolve the chlorides in water and deposit the zinc electrically; Richards (Eng. Pat.

13982, 1885) dissolves the oxide of zinc, together with the chlorides, in the minimum quantity of hydrochloric acid, and after evaporation electrolyses the concentrated solution of zinc chloride (cf. Ingalls, *Metallurgy of Zinc*, 2nd ed. 578).

The electrolytic method has also been applied to the treatment of the zinc scum obtained during desilverising, and Rosing states (*Dingl. poly. J.* 263, 87) that this method is the most suitable for the purpose of any process at present known. The powdered scum is spread on a lead plate at the bottom of a wooden vat which is filled with a solution of zinc sulphate. The lead plate acts as anode, and when the current is passed, zinc deposits on the cathode, and a corresponding weight of zinc is dissolved from the scum. When the surface zinc has been thus removed, the residual mass is dried and heated to redness in a cupellation furnace and again electrolysed.

The quantity of hydrochloric acid annually used for pickling in the country is very great, as a number of firms engaged in the galvanising trade each require some thousands of tons of commercial muriatic acid (26-30 p.c.) per annum, but no statistics on this point are available. When the works are situated near the sea the waste pickle is readily disposed of, but the Midland manufacturers have during the last few years met with increasing difficulty in getting rid of their waste acid. The nuisance has become intolerable, and costly litigation has been undertaken by the local corporations to enforce some efficient system of treatment. Hitherto the usual system has been that of neutralisation with lime and subsequent filtration, with or without subsequent roasting of the ferrous precipitate, to convert it into red oxide of iron. Turner (Eng. Pat. 1889, 1890) introduced a method of recovering the hydrochloric acid, and the process has been in operation in South Staffordshire for over 30 years. The waste liquor, which consists of an acid solution of ferrous chloride, contains slightly under 10 p.c. of iron and about 15 p.c. of acid, chiefly in combination. The liquor is allowed to trickle slowly into a fire-brick reverberatory furnace of special construction; this is connected with condensers for the acid, which are arranged in the ordinary way. A bath of concentrated ferrous chloride solution is maintained in the furnace and thus prevents leakage, as the saturated solution penetrates any crack, and solidifies in coming in contact with the cool exterior of the furnace. The ferrous chloride is more strongly heated near the firebridge, and decomposes thus:—

Hydrochloric acid is thus recovered and used over again, while the ferric oxide is raked out of the furnace and used as fettling in the puddling process. The fuel consumption is about 4 cwt. of gas coke per ton of waste liquor treated.

When sulphuric acid is used for pickling, the solution is evaporated and crystallised to produce copperas (commercial ferrous sulphate), for which there is a limited demand. In a few instances the copperas is afterwards decomposed by heat for the production of rouge, and other varieties of bright-red ferric oxide.

Dry galvanising.—In the process known as 'sherardising,' introduced by S. Cowper-Coles, the articles which are to be coated with zinc are carefully cleaned and placed in closed boxes with zinc in a state of fine division. The boxes with their contents are then heated to a temperature insufficient to cause the zinc-dust to melt, and the vapour evolved gradually combines with the surface of the iron, and produces a closely adherent and protective coating of zinc. This process has been applied on a considerable scale, and is specially suited for articles which have sharp patterns upon their surfaces, or crevices which would be obliterated or filled up with zinc in the usual processes of dipping in molten zinc. The surface is somewhat less bright than usual, but is pleasing in appearance, and its wear is quite satisfactory.

Electro-galvanising.—Iron or steel articles are now also frequently covered with zinc by deposition, with the electric current, from a neutral solution of zinc sulphate, or from zinc salts dissolved in caustic alkali. This process is not used for the general run of galvanising work, but more particularly for articles which are in a partly finished condition, or which are of such a special size or shape as to render the ordinary process unsuitable. Zinc coatings can thus be obtained which are quite satisfactory in wear and appearance, but they are apt at times to be soft and spongy, and not to adhere firmly to the surface of the iron. They are also more than usually subject to trouble from the development of black spots on the surface when exposed to moist air.

The nature of the zinc coating obtained by various processes has been studied in detail by Guertler, *Metallographie*, 1911, 353. The most complete account of the various processes of galvanising is that given by M. A. Sing (*Le Zingage du fer et de l'acier*, *Revue de Metallurgie*, 1912, 1, 78, 160).

ALLOYS OF ZINC.

Zinc readily unites with most metals when the temperature is raised sufficiently to insure fusion. The binary alloys of zinc are generally white, crystalline, brittle materials of limited importance. These alloys are usually of uniform composition; with lead and with bismuth, however, zinc unites at a temperature above its melting-point, but the alloys separate on cooling into two distinct layers, the upper layer in each case consisting of nearly pure zinc. The most important series of binary alloys of zinc is the copper-zinc (or brass) series, which is separately described.

With aluminium zinc readily unites when the metals are melted together in any proportions. The constitution of the series of alloys has been studied by Heycock and Neville (*Chem. Soc. Trans.* 1897, 389); Shepherd (*J. Phys. Chem.* 1906, 9, 504); Ewen and Turner (*Journ. Inst. of Metals*, 1910, 2, 140); Rosenhain and Archbutt (*Phil. Trans. A*, 211, 315; also 10th Report Alloys Research, 1912); Eger (*Intern. Zeitsch. Metall.* 1913, 4, 29); Bauer and Vogel (*Mitt. K. Mat. Prüfungsamt*, 33, 146); Tanabe (*J. Inst. Metals*, 1924, 32, 415). Their thermal expansion has been measured by Smirnoff (*Compt. rend.*, 1912, 155, 351). The phases

which are recognised are α , which is zinc, or a solid solution containing less than 1 p.c. of aluminium; β , which is a definite compound, probably Al_2Zn_3 ; and γ , which is a solid solution of zinc in aluminium, and may contain as much as 40 p.c. of zinc. There is one eutectic, with 95 p.c. of zinc, melting at 380° , there is also a small break on the freezing-point curve at 85 p.c. of zinc, and an inversion at 256° , when the β -phase on cooling breaks up into α and γ . The compound Al_2Zn_3 appears to be stable only above 256° (Fraenkel and Goetz, *Z. Metallk.* 1925, 17, 12). The commercially interesting alloys are at the aluminium end of the series, and these have assumed very considerable importance in recent years (*cf.* Levi-Malvano and Marantonio, *Gazz. chim. ital.* 1912, 42, 1, 353; Carpenter and Edwards, *Intern. Zeitsch. Metall.* 1912, 2, 209). The so-called aluminium (used for motor cylinders and many purposes usually contain about 10 p.c. of zinc; not unfrequently a few p.c. of copper or other metal or metals, and the residue aluminium. These alloys are rather more fusible than pure aluminium and are stronger and work better. They are also slightly cheaper. Alloys containing up to 25 p.c. of zinc can be rolled hot, at suitable temperatures, and material with tensile strength up to 34 tons per sq. in. obtained. The strength of these alloys is thus equal to that of mild steel, and as their density is only about 3.32 they have found considerable applications where lightness and strength are required. Tensile tests have also been made on large crystals of an alloy containing 15.6 p.c. of zinc (Elam, *Proc. Roy. Soc.* 1925, A, 109, 143). Duralumin, the light alloy used for aircraft and similar purposes, is of this class; its properties depend not only upon its composition, but also upon suitable mechanical and heat treatment. In sand-cast alloys the maximum tensile strength is obtained with from 20 to 60 p.c. of aluminium, and the maximum hardness is within the same range. The tensile strength of all these alloys rapidly falls as the temperature rises. They are, therefore, not suitable for use when subjected to the effect of heat. See also Vol. IV. p. 295.

The density of the zinc-aluminium alloys agrees closely with that calculated from their composition; chilled castings are slightly less dense than theory would indicate, and sand castings slightly lighter than chilled castings. The volume changes which occur on alloying are, however, not such as can be detected without careful tests. According to O. Bauer and W. Heidenhain (*Mitt. Materialpruf.* 1923, 41, 50), the relation between the contraction on freezing and the constitution of aluminium-zinc alloys has been determined. In all samples tested the chill-cast alloys showed a greater total shrinkage (from liquid to solid at ordinary temperature) than the sand-cast alloys. The great difference in the shrinkage of chill-cast and sand-cast zinc practically disappears when only 0.5 p.c. of aluminium is added to the metal. Further additions of aluminium reduce the contraction to a minimum at 2.5 p.c. Al, then increase that of the chill-cast alloy to a maximum at the eutectic point without, however, influencing that of the sand-cast metal. From the point at which the primary separation of Al_2Zn_3 from the liquid mass begins the contraction of both sand-cast

and chill-cast alloys falls, reaching a minimum at a composition corresponding to Al_2Zn_3 , then slowly rises to a maximum at 55 p.c. Al (limit of γ -mixed crystal phase), falls somewhat, and finally rises steeply to the high value of pure aluminium. The curve in general provides a confirmation of Rosenhain and Archbutt's equilibrium diagram for the aluminium-zinc alloys (J. Soc. Chem. Ind. 1911, 1166) and evidence for the existence of the compound Al_2Zn_3 (J. Soc. Chem. Ind. 1924, 43, B. 520). Zinc-copper-aluminium alloys are only satisfactory for use at ordinary temperatures, as they become brittle on heating; an alloy containing 12.5-14.5 p.c. Zn and 2.5-3 p.c. Cu has a tensile strength of more than 11 tons per sq. in., and an elongation of 4 p.c. on 2 in. at 15°; the tensile strength falls to 4 tons at 250°, and to 1.5 tons at 350°. Some copper zinc-aluminium alloys of high zinc content exhibit the phenomena of season cracking if annealed at too high temperature, but this tendency in the over-annealed metal may be greatly overcome by hot working, so as to effect a total reduction of cross-sectional area of 50 p.c.; the alloys of this series also corrode badly on exposure to seawater, although they are stable in the air (Alloys Research Committee, 11th Report, J. Soc. Chem. Ind. 1921, 851 A.).

Magnesium and zinc form a definite compound MgZn_2 , which can be distilled unchanged.

With *antimony*, zinc readily unites in all proportions; the resulting alloys are brittle, and exhibit a close-grained, dark-grey fracture when much antimony is present; when antimony is in excess, the surface of the alloys readily tarnishes during the process of casting, and the ingot becomes coated with a dark-grey crust of oxide. When the constituent metals are present in about equal proportions, surface colorations of great beauty can be obtained by oxidation, the tints obtainable including yellow, green, red, purple, and blue. A small proportion of antimony renders the surface colour of cast zinc distinctly more blue than usual, and with care the presence of 0.5 p.c. of antimony can be readily detected by this test. The usual colour of the surface of ingots, of equal parts of antimony and zinc, is a bright sky-blue, and the alloy has the peculiar property of marking glass (Turner). Antimony-zinc alloys are readily fusible, and in this respect the influence of antimony is quite different from that of arsenic or phosphorus, both of which raise the melting-point of zinc. The most stable compound of antimony and zinc appears to be ZnSb , m.p. 537° (Tammann and Dahl, Zeitsch. anorg. Chem. 1925, 144, 1). Zinc-antimony alloys have met with an application for the production of thermopiles, for which purpose they are well suited.

With *bismuth*, zinc unites when the metals are melted together, but on cooling the alloy separates into two layers, the upper consisting of zinc containing bismuth, while the lower layer consists of bismuth containing zinc. The composition of the two layers varies with the temperature, the solubility of each metal in the other steadily increasing as the temperature rises until at about 850° the whole is of uniform composition (Heycock and Neville, Chem. Soc. Trans. 1897, 71, 390). With *gold*, zinc forms a series of alloys which are pale yellow, with

excess of gold, and greenish as the proportion of zinc increases; all these alloys are more or less brittle. In the production of jewellery part of the copper used in the preparation of the gold alloys is often replaced by brass, as the colour of the resulting gold can be thus improved, while the cost of the alloy is slightly reduced. The presence of much zinc renders the gold hard and difficult to work, and as the zinc is volatile at high temperatures this alloy is not suitable for use where the article has to be reheated during manufacture. The compound AuZn , with 75.1 p.c. Au, can be obtained by distilling off the excess of zinc from gold zinc alloys, in a vacuum, at 500° (see Groves and Turner, Chem. Soc. Trans. 1912, 585).

With *iron*, zinc forms a series of alloys which are generally white, hard, and brittle. With not more than 5 p.c. of iron the alloys are close-grained and darker in colour than pure zinc; such alloys are produced in the process of galvanising, and are known as 'hard zinc.' With more iron the character of the alloy varies according to the method of preparation. The ferri-ferrous residue left on liquating 'hard zinc' is very friable, and readily crushes into a coarse dust, consisting of bright flakes or spangles; on the other hand, the material obtained by fusion is compact, white, hard, and brittle. The alloy of zinc and iron obtained by saturating zinc near to its temperature of volatilisation with iron is not attracted by a magnet; it does not rust, nor give sparks by friction or blows. It is dense in structure, but is only semi-metallic in fracture, and contains about 22 p.c. of iron. These alloys have a somewhat important application in the preparation of 'delta metal,' and also of Aich, stereo, and Gedge's metal, all of which are yellow brasses containing about 60 p.c. of copper and nearly 40 p.c. of zinc. The addition of iron to these brasses, first suggested by Keir in 1779, imparts special hardness, toughness, tenacity, and wearing properties, while the alloy can be rolled either hot or cold, and the constituents of the mixture are relatively cheap. The proportion of iron present usually varies from about $\frac{1}{4}$ to 4 p.c., according to the purpose for which the alloy is to be applied. The zinc-iron alloy can be prepared by one of the following methods:—

1. By immersing clean iron wire, or sheet, in a bath of molten zinc heated to near its boiling-point. The addition of a little charcoal and some solid ammonium chloride assists the action. Where the presence of a little tin in the alloy is not objectionable (as for stereo-metal) a convenient method is to employ clean tin-plate scrap; the coating of tin readily unites with the zinc and leaves a clean surface of iron exposed to the action of the molten metal.

2. In order to reduce the waste of zinc usually accompanying the production of such alloys, a zinc of high boiling-point may be advantageously used in some cases. Bull (Eng. Pat. 4086, 1888) proposed the addition of phosphorus or arsenic for this purpose, while the addition of a little copper to the zinc assists the action without the introduction of any injurious constituent.

3. Alloys rich in iron can also be obtained by liquating the 'hard zinc' from galvanising works, and strongly heating the ferri-ferrous

residue in a closed crucible. The excess of zinc is volatilised, and the percentage of iron increases with the temperature employed. The alloys actually used in practice contain from about 7 to nearly 30 p.c. of metallic iron.

The equilibrium of the iron-zinc series has been studied by V. Vegesack (Zeitsch. anorg. Chem. 52, 1907, 30). The diagram is somewhat complicated. At the iron end there is a series of solid solutions in α , β , and γ iron with a maximum of about 35 p.c. of zinc at 1100°. At the zinc end two compounds are recognised, FeZn_2 (or perhaps FeZn_3) and FeZn_{11} . These compounds undergo decomposition at 777° and 662° respectively. W. Guertler (Metallographic, 1911, 353) has recognised the compound FeZn_3 as an intermediate, electro-negative layer in the coating of galvanised iron, and occurring between the iron and the zinc coating. He has also recognised crystals of FeZn_2 in the external coating of zinc (cf. Vigouroux, Ducehiez and Bourbon, Bull. Soc. chim. 1912, [iv.] 11, 480; Raydt and Tammann, Zeitsch. anorg. Chem. 1913, 83, 257).

With *cobalt*, zinc combines to form a definite compound CoZn_4 . Alloys of these two metals, containing more than 81.6 p.c. of zinc, are non-magnetic and become more brittle as the quantity of zinc diminishes. When powdered and treated with cold 1 p.c. hydrochloric acid or dilute nitric acid they leave a residue of CoZn_4 , D° 7.43 (Ducehiez, Bull. Soc. chim. 1911, [iv.] 9, 1017).

With *manganese*, zinc forms MnZn_2 and MnZn_3 , the fusion diagram being similar to that of the zinc-iron alloys. The alloys are hard and brittle; those containing 5–20 p.c. of manganese are porous, but those with a greater proportion of manganese are more compact (Parravano and Perret, Gazz. chim. ital. 1915, 45, i. 1).

With *lead*, zinc readily combines when the two metals are melted together, but on cooling the mixture, or allowing it to remain at rest, the zinc collects as a layer at the upper surface, while the lead is found at the bottom of the mass. Neither of the metals is, however, quite pure, for the lead on cooling retains 1.6 p.c. of zinc, while the zinc retains 1.2 p.c. of lead (Percy, Metallurgy, 90). These proportions vary according to the method of treatment and the temperature employed. Thus E. Kraut has examined the behaviour of zinc containing lead on remelting (J. Soc. Chem. Ind. 5, 537). The sample was melted, well mixed, and a quantity removed and granulated. The residue was allowed to cool slowly, and the top, middle, and bottom of the mass separately analysed. The top contained 0.943 p.c. of lead, the middle 2.847 p.c., and a small quantity at the bottom as much as 4.121 p.c.; whilst the original zinc contained 1.543 p.c. of lead. In these experiments only 2 kilos. of metal was employed; on the large scale the separation of the two metals is still more complete.

The rolled zinc of commerce is a nearly saturated solution of lead in zinc, and usually contains about 1 p.c. of lead. An excess of lead injuriously affects the rolling properties; hence it is usual when rolling Continental zinc to remelt it in a reverberatory furnace with an inclined bed. The metal is allowed to remain fluid at a temperature a little above its melting-

point, and the zinc is ladled off from the top from time to time. The excess of lead separates and collects as a layer in the lower end or 'sump' of the furnace, beneath the zinc, and is removed at suitable intervals.

On strongly heating lead-zinc alloys, the excess of zinc is at first volatilised, but as the temperature rises both lead and zinc distil over together. This curious volatility of lead in the presence of zinc is doubtless the cause of the occurrence of lead in commercial zinc, obtained from ores containing lead. The presence of a small proportion of zinc in commercial lead communicates hardness and allows the lead to receive a good polish without destroying its malleability.

With *mercury*, zinc readily unites to form a series of white brittle amalgams which become pasty when mercury is in excess. Zinc amalgams are easily obtained by mixing mercury with molten zinc, or by adding zinc to mercury heated nearly to its boiling-point. Zinc plates for galvanic batteries are coated with mercury by first cleansing the surface of the zinc with dilute sulphuric acid and then rubbing the mercury over the clean surface. An amalgam of zinc and tin is used on the rubbers of frictional electrical machines. (On the literature of zinc-amalgams v. J. Soc. Chem. Ind. 9, 512; cf. Hildebrand, 8th Inter. Cong. Appl. Chem. 1912, 22, 117).

For the use of zinc amalgam in the evolution method for the determination of sulphur in iron and steel, see Teruo Ashida (Memoirs of the Coll. of Science, Kyoto Imperial University, Series A. Vol. 7, No. 1983).

With *silver*, zinc does not very rapidly unite at the melting-point of the latter, but at higher temperatures the metals readily combine, forming a series of alloys which are whiter than zinc, and the use of which has been proposed for coinage and other purposes. With 5, 10, or 20 p.c. of zinc, silver forms white ductile alloys, which can be rolled like standard silver, and which are more fusible than the corresponding copper alloys (Percy, Gold and Silver, 169–171; cf. Heycock and Neville, Chem. Soc. Trans. 1897, 71, 407; Carpenter and Whiteley, Intern. Zeitsch. Metall. 1912, 3m 145).

When lead which contains silver or gold is melted with zinc and allowed to cool, the zinc separates, rises to the top, and solidifies first. This solid crust of zinc contains the precious metals, and this fact was applied by Parkes in the well-known process for desilverising argentiferous lead. The zinc scum is distilled to remove the zinc, much of which is recovered in the metallic state. The silver is melted, refined, and cast into ingots. The separation of the two metals is practically complete at 700° in a vacuum (Groves and Turner).

According to W. G. Traub (Am. Electrochem. Soc. Trans. 42, p. 55; Disc. 59, 1922) experiments were made to determine the cause of the disappearance of certain metals that had been deposited on zinc. The results indicate that copper, brass, gold, and silver are diffused into zinc; whereas nickel, which does not diffuse into zinc, can be used as a preventive against diffusion of other metals deposited over it (Sci. Abstr. 1924, 27, 300).

With *tin*, zinc readily unites in all propor-

tions, the resulting alloys being generally harder than tin but softer than zinc. The colour of the alloys is in all cases white, and the fracture is crystalline, although its appearance varies with the mode of preparation. The alloys of tin and zinc are not quite uniform in composition, as the tin tends to separate and collect at the bottom on cooling. Tin-zinc alloys are used for castings of patterns for ornamental purposes. A detailed description of these alloys, based on the work of Guettier and Rudberg, is given in Hiorns' *Mixed Metals*, 249-253.

With cerium, zinc forms two compounds Ce_2Zn and Ce_3Zn (Clotofski, *Zeitsch. anorg. Chem.* 1920, 114, 1).

The vapour pressures of molten cadmium and of its alloys with zinc have been measured at two temperatures, and Raoult's law is found to hold. The internal pressure of cadmium, indicated by compressibility and expansion coefficients, is much the same as that of zinc at the temperatures investigated (A. C. Egerton and F. V. Raleigh, *Chem. Soc. Trans.* 1923, 123 3321, *J. Soc. Chem. Ind.* 1923, 10, 2, 55).

NICKEL SILVER, BRASS, &c.

In addition to the binary and other zinc alloys above mentioned, zinc enters into the composition of a number of alloys containing three or more metals, of which the following are the most important.

Nickel silver (also known as German Silver, Packfong, White Copper, Electrum, Nevac Silver, &c.) consists of copper, zinc, and nickel. It is an alloy of white, or nearly white colour, of high tenacity, and capable of being cast, rolled, spun, and otherwise worked. One of its most important properties is its relative permanence in the air, and this has led to the use of the alloy on a very extensive scale. It usually contains about 50-60 p.c. of copper, the proportions of zinc and nickel varying according to the price and use of the alloy; the zinc is seldom less than 11 or more than 30 p.c. of the whole. For castings a little lead is frequently added. Generally an alloy of about equal weights of zinc and nickel is first prepared, and to this 'temper' the necessary quantities of copper and brass are added to give the required composition. A good description of the copper-nickel-zinc alloys will be found in Hiorns' *Mixed Metals*, 235-248.

One of the chief applications of nickel silver is in the electro-plate trade, for the production of articles of which teapots, forks, and spoons may be taken as examples. The alloys are melted in crucibles, deoxidised usually with manganese, cast into strips in metal moulds, and rolled, with several annealings, to the required gauge. For the production of ductile alloys pure metals must be used, and the temperature and character of the annealings carefully regulated. The character of the silver deposit on such articles has been studied by McWilliam and Barclay (*Inst. of Metals*, 1911, 1, 212), who conclude that when the proportion of nickel exceeds 14 p.c. the silver is more liable to strip off irregularly in actual use. With more nickel the strength and hardness increase and the alloy more nearly resembles silver in colour. Alloys containing

10-22 p.c. of nickel are specified for best work, and by suitable methods adherent coatings of silver of excellent quality can be obtained (*ibid.* 226).

Part of the tin in *gun metal* and in *bearing metal* is frequently replaced by zinc, as it is found that the density and wearing properties of the alloy are thereby increased (*v. Bronze*, art. Tin). For the same reason the bronze coinage of this country contains 1 p.c. of zinc. Zinc is also present in some varieties of aluminium bronze, and phosphor bronze, in manganese bronze, and other similar alloys. The 'Biddery Ware,' manufactured in India, usually contains about 90 p.c. of zinc together with copper, lead, and tin in different proportions.

Copper alloys—Brass. *History.*—Although the word brass frequently occurs in the Old Testament, there is little evidence that an alloy of zinc and copper was known in early times, unless, indeed, the suggestion be accepted that brass was sometimes accidentally produced in the manufacture of copper. The word translated 'brass' might equally well be rendered copper or bronze, both of which were in common use for a considerable period before the introduction of copper-zinc alloys (*v. Bronze*, art. Tin).

There is abundant evidence, however, that brass was known to the Romans about the beginning of the Christian era; that it was used for coinage purposes, and that it formed one of the yellow alloys known as *orichalcum*. The analytical and historical evidence on these points have been summarised by Dr. Percy (*Metallurgy*, i. 518-528; *cf. Gowland, Presidential Address, Inst. of Metals*, 1912). In the middle ages the Germans were famous for the production of brass, which was imported into this country chiefly in the form of sheet or *latten*, which was employed for the 'brasses' of churches, particularly in the Eastern counties. Over 4000 such brasses are known to exist in various churches, &c. in the United Kingdom, which is far richer in this respect than any other country. The first brass manufactory in England is stated to have been erected by a German in Surrey about the middle of the seventeenth century. Brass works were started in Bristol in 1702, whilst the first works for making brass in Birmingham (now the centre of the brass trade) were erected about 1740 by Turner. Up till the middle of last century the only method used in the production of brass was the calamine, or cementation, process, in which copper, in the form of bean shot or sheet, was heated in crucibles in contact with calamine and carbon, with the result that zinc was liberated and volatilised, being afterwards absorbed by the copper. The brass thus produced was then melted down and cast. This process was slow and laborious, and only yielded a brass tolerably rich in copper. In 1781 James Emerson patented the direct production of brass from copper and zinc, although there is evidence that the method had been previously used to a limited extent. The calamine process was gradually superseded by the direct method of production; the last calamine brass works in this country were closed about 1850. Some of the most important factors in the development of the brass trade have been the introduction of rolling mills in the early part

of last century, with the subsequent application of powerful machinery; the application of the stamp and die in 1769, whereby articles were produced more rapidly, with better finish, and with less metal than by the old process of casting; the introduction of gas fittings in the early part of the nineteenth century; the use of brass and copper tubes in locomotives and marine engines; the introduction of yellow metal sheathing; of brass cases for cartridges; the extruding and hot stamping of brass; and the extended use of engineers' brass work and steam and water fittings, and lastly the applications to electric fittings. These and many other circumstances have resulted in an enormous development of the brass trade, so that there are normally employed in the brass trade of Birmingham alone over 35,000 persons (male and female), while the consumption of metal is valued at 4 millions sterling (*v. A Short History of the Brass Trade*, J. W. Davis; also *Encyc. Brit. art. Brasses*; Thomson, *Hist. of Chemistry*, i. 55, 62, &c.; *Midland Hardware District*, 228-240; Percy, *Metallurgy*, 504; Holzapfel's *Mechanical Manipulations*, 312; *Useful Metals and their Alloys*, 566).

General properties of zinc-copper alloys.—

Zinc and copper unite in all proportions, the resulting alloys being of remarkably uniform composition throughout the mass (Laurie, *Chem. Soc. Trans.* 53, 106; 55, 677). The experiments of Tilden (*J. Soc. Chem. Ind.* 9, 84) also show the great uniformity in composition of commercial sheet brass, although on the other hand Hiorns (*Mixed Metals*, 107) gives analyses showing the copper to be less at the top than at the bottom of ingots of cast brass. The alloys containing upwards of 60 p.c. of copper are red or red-yellow in colour; those containing less than 48 p.c. of copper are grey or white; the intermediate alloys are yellow. The hardness of the alloys is usually greater, while the melting-point is higher, and the density greater, than that calculated from the mean of the constituents. Copper-zinc alloys containing 7-28 p.c. Cu expand to a greater or lesser extent on solidification, the maximum expansion occurring with the alloy containing 15 p.c. Cu. The range of composition in which marked expansion takes place has a large freezing interval, and chill-cast alloys within this range exhibit to a considerable degree the phenomenon of inverse segregation. The degree of segregation in chill-cast bars is proportional to the expansion that takes place in sand-cast bars and has the same range and maximum copper content. The force of expansion in alloys containing 10-20 p.c. Cu is sufficiently great to break the crucible in which the metal is cooled, and the resulting metal contains many cracks and voids, whilst its hardness and elastic limit are low. Microscopical examination of alloys within this range revealed in all cases a very indefinite structure containing many minute cracks and holes; this appears to be due to the fact that these alloys consist almost entirely of ϵ , which has the property of expanding and becoming very soft, so that the crystal boundaries become obliterated. The expansion of the ϵ phase proceeds very quickly after the alloy has cooled through the β peritectic line (K. Iokibe, *Inst. of Metals*, 1924; *J. Soc. Chem. Ind.* 1924, 43, B. 297). The

addition of zinc to copper produces remarkable alterations in the working properties of the product, varying, however, with the proportion of zinc present. Thus, pure copper can be rolled hot or cold, although in the latter case frequent annealing is necessary, and rolling hot is much cheaper and more expeditious. The addition of only a trace of zinc renders copper 'red short,' although it does not interfere with the malleability of the metal when cold. Hence alloys which contain from about 62 to 100 parts of copper p.c., and the residue zinc, are not generally rolled hot, or if so rolled require special treatment. Usually these alloys are rolled cold, and are annealed and pickled from time to time as the metal becomes hard and brittle from the work put upon it. But alloys with about 60 p.c. of copper can be rolled either hot or cold, and the cost of production is thus reduced. These alloys are, however, less ductile and tough than those which contain more copper. Their tensile strength is greater, but their ductility less than with alloys higher in the series. The alloy of 60 parts of copper and 40 of zinc was patented by Muntz for the production of sheathing for wooden ships, and is now largely prepared under the name of 'yellow metal,' for the production of the cheaper varieties of brass sheet, tubes, and wire. The standard size of yellow metal sheets is 14 by 48 ins., and the thickness is returned according to the Birmingham metal gauge. Alloys containing about 56 to 58 p.c. of copper, and consisting almost entirely of the β phase, are extruded into rods, while red hot, by means of suitable presses. Such alloys will forge at a red heat. Alloys of about this composition are used for material which has to be turned or otherwise finished by automatic machinery. According to Heathcote, the presence of from 1.5 to 2 p.c. of lead in the alloy gives the best results when machining (*J. Inst. of Metals*, 1917, 17, 56). Alloys containing about 50 p.c. of copper are light yellow in colour; but cannot be rolled either hot or cold. The chief application of alloys containing rather more than half their weight of copper is for the production of 'brazing' solder for use with copper, brass, &c. These alloys form what is usually known as 'hard' solder, in contradistinction to lead-tin alloys or 'soft' solder. But in the brass trade different varieties of solder are used, containing from about 45 to 56 p.c. of copper, according to the temperature to be employed. The brazing solders containing more copper are called 'hard,' and those with more zinc 'soft.' The solder most commonly employed contains about 51 p.c. of copper, and is usually sold in the form of powder, which is prepared by heating a mass of the alloy to a particular temperature below its melting-point, when it is struck a sharp blow with a mallet. At this temperature the alloy is very friable, and readily crumbles into powder when treated as above described. If it is too hot or too cold it cannot be powdered in this way.

With more than 50 p.c. of zinc the alloys lose their yellow colour and become white, brittle, and more fusible. Though all these white alloys are brittle when hot or when cold, they can usually be laminated at some intermediate temperature, and in this respect they

zinc. This proper temperature varies according to the proportion of copper present, being as low as 150° in zinc, and at a red heat, probably about 600° , in yellow metal. As the copper increases beyond 60 p.c., as before explained, brass can no longer be rolled hot, but is laminated in the cold with repeated annealing.

For the corrosion of Muntz metal in sea water, see W. Donovan and T. E. Perks, *J. Soc. Chem. Ind.* 1924, 43, 72 T. For the corrosive action of brackish waters on metals, see T. E. Perks, *J. Soc. Chem. Ind.* 1924, 43, 75 T.

According to Mallet (*Construction of Artillery*, 82), the alloy CuZn_2 , containing about 33 p.c. copper and 67 p.c. zinc, is used for watch-maker's brass, and possesses the greatest tenacity of the whole series. This statement has been copied into many well-known works on the subject, but it is evidently an error. Laurie has shown by his investigations on the electro-motive force of zinc-copper alloys (see above) that only one definite alloy exists in this series. This compound is white, hard, and brittle, and corresponds very closely in composition to Mallet's alloy above mentioned. All other zinc-copper alloys may be considered as solidified solutions of this definite compound in excess of one or other of the constituent metals. Guertler (*Zeitsch. anorg. Chem.* 1906, 51, 397; 1907, 54, 58) and Murray and Turner (*J. Inst. of Metals*, 1909, 2, 131) support the view of only one definite compound in the copper-zinc series, viz. Cu_2Zn_3 with 39.36 p.c. Cu. This compound is a brilliant white brittle substance, harder than mild steel. Of itself it is of little or no practical value, but by its union with various proportions of copper, which alone is too soft, a whole series of alloys is obtained which possess most valuable and remarkable graduated properties.

The equilibrium of the copper-zinc series was studied by Roberts-Austen (4th Report Alloys Research); Shepherd (*J. Phys. Chem.* 1904, 8, 421), Tafel (*Metallurgie*, 5, 13), Hudson (*J. Soc. Chem. Ind.* 1906, 503), Murray and Turner (*J. Inst. of Metals*, 1909, 2, 103), and Carpenter and Edwards (*ibid.* 1911, 5, 127). The latest form of the equilibrium diagram of this series has been given and discussed by Rosenhain in the article on METALLOGRAPHY, and will, therefore, only receive brief reference here. The alloys, which are of commercial importance, contain from about 45 to 100 p.c. of copper. Within this range there are three constituents which are respectively designated by the Greek letters α , β , and γ . The α constituent is a solid solution of zinc in copper, the maximum content of zinc being about 36 p.c. at 400° . The γ constituent was regarded by Shepherd as a solid solution, but by Murray and Turner as the compound Cu_2Zn_3 , containing about 40 p.c. copper. The β constituent contains about 53 p.c. copper. It has the properties of a solid solution, but was believed by Carpenter (*J. Inst. of Metals*, 1912) to be an intimate mixture of α and γ below a critical temperature of 470° , but this view is not now generally accepted. This critical temperature is noted with alloys containing from 60 p.c. of zinc down to 28 p.c., and probably less. The α phase is relatively soft and ductile: the β phase is harder and more brittle, while the γ phase is still harder, and practically has no ductility. It can be

readily powdered in a mortar. The effect of adding zinc to copper is, therefore, as shown by Charpy, to increase the tenacity and to diminish the ductility. Beyond 40 p.c. the tenacity very rapidly falls away again, whilst the ductility is diminished after 30 p.c. Hence where ductility and strength are required together, as with cold-drawn tubes, or cartridge cases, about 70 p.c. copper is preferred. The chief commercial alloys may be classed as follows (Hudson):—

1. 100–71 p.c. Cu. Consist entirely of α at all temperatures.
2. 71–64 p.c. Cu. Entirely α below 400° ; $\alpha + \beta$ above.
3. 64–63 p.c. Cu. Consist of $\alpha + \beta$ at all temperatures.
4. 63–53.5 p.c. Cu. $\alpha + \beta$ at low temperatures; β only at some higher temperatures.
5. 53.5–51 p.c. Cu. Consist of β entirely at all temperatures.
6. 51–40 p.c. Cu. $\beta + \gamma$ at low temperatures β only at a higher temperature.

It will be noted that the proportion of the β constituent increases as the temperature rises, and this fact has important bearings on the heat treatment of brass. The brittle ranges in the brasses have been studied by D. Bunting (*Inst. of Metals*, 7, 31).

Cast brass. All brass is now made by melting together copper and zinc, but the term 'cast brass' is applied when the article to be made receives its form in the mould, and does not require to be afterwards rolled, drawn, hammered, or spun. For this purpose the charge is melted in graphite or clay crucibles, which usually contain about 90 lbs. of metal, and which are heated in small wind furnaces by coke. Generally each furnace contains but one pot, but sometimes two or four pots are placed in a single furnace, which is made proportionately larger in such cases. In Birmingham clay crucibles were formerly used for brass, and plumbago for bronze castings. Larger crucibles, holding 250 lbs. of metal, are often used in big foundries. Small cranes are then provided. Tilting furnaces are also now very frequently employed. Electrically heated furnaces are used in many of the larger brass works in the United States. In practice it is necessary to add a quantity of scrap brass to the charge, and this is generally introduced first into the red-hot crucible together with a small quantity of flux, which is added to remove the oxide and dirt adhering to the scrap. When only new metal is used the flux is either much reduced or altogether omitted. The fluxes most commonly employed are ground fluor-spar, together with more or less glass, and *sal enizum* or acid potassium sulphate. Calcined borax, often with the addition of some boracic acid, is also used as a flux. When the scrap is hot the copper is charged into the crucible, usually in the form of ingots, though occasionally bean shot copper is used. After the copper has thoroughly melted, the zinc is cautiously added in as large pieces as possible. The use of large pieces of zinc reduces the loss, and moderates the violence of the combination. In any case considerable heat is produced by the union of zinc and copper, and some of the zinc burns with a dazzling brilliancy. After allowing the crucible to remain in the furnace for a short time to permit

the metal to become sufficiently fluid, it is poured into moulds, which for brass casting are generally of 'green' sand. While the brass is hot, zinc gradually volatilises and burns at the mouth of the crucible, forming zinc oxide; this produces the white fume which fills the casting house while the metal is being poured, and as a protection against the deleterious effects of inhaling the fume it is customary for the workman to keep his mouth and nostrils covered with a cloth. Regulations are now in force to ensure the proper ventilation of brass foundries. When the metal has set, the castings are turned out and dipped while warm into water, which detaches most of the adhering sand; the processes of dressing, grinding, polishing, dipping, and burnishing are necessary to give the required surface, while the finished article is lacquered to preserve it against atmospheric influences. The proportion of copper in cast brass varies considerably according to the purpose for which it is required; in some cases cheapness is of prime importance, in others the metal must 'dip' well when immersed in acid, while not unfrequently the shade of colour of the resulting alloy is of the utmost moment. Best cast brass generally contains from 70 to 75 p.c. of copper; ordinary good English brass 66·6 p.c. (i.e. 2 p.c. of copper to 1 of zinc); while common cast brass contains about 62 p.c. of copper. A little lead is generally added in preparing cast brass; this gives sounder castings and produces a metal which turns much better in the lathe than ordinary brass. Although not unfrequently as much as 2 p.c. of lead is added to the charge, most of this is removed by oxidation and usually only about 0·3-0·5 p.c. remains. The loss of metal in melting and casting is usually about 3 p.c., but this is greater when much small scrap is used. It may be added that in the preparation of cast brass it is not so necessary to ensure the absence of very small quantities of metals such as antimony, bismuth, and silver as is the case when the alloy has afterwards to be rolled or drawn. When special ductility or malleability is required in the final product, it is of the utmost importance that the purest obtainable materials should be employed.

When alloys of the copper zinc series are cast in bars in sand moulds, and the length of the bars during cooling is observed by means of an extensometer, it is found that in some cases marked expansion occurs, while with other compositions there is little or no expansion. There are three maxima, which in order of magnitude occur with 15, 80, and 50 p.c. of copper respectively. The nature of the marked expansion with about 15 p.c. of copper has been studied by K. Iokibe (*Inst. Metals Jour.* 31). It does not occur if the alloys are cooled quickly; in the rapidly cooled alloys there is marked 'inverse segregation,' i.e. the copper concentrates towards the middle of the ingot. The series has four maxima on the hardness curve, which are with 40, 80, 65, and 10 p.c. respectively. The 40 p.c. alloy is exceptionally hard (Turner and Murray, *J. Inst. of Metals*, 1909, 2, 98; F. W. Harris, *Inst. of Metals J.* 28, 327).

Sheet brass. One of the most important applications of brass is for the production of sheets, as sheet brass is not only needed for a multitude of useful and ornamental purposes

itself, but it forms the starting-point for the manufacture of the greater part of the brass wire and tubing that is dealt with in commerce.

For the production of 'yellow metal' it is customary to prepare the alloy by melting copper on the bed of a small reverberatory furnace and adding the requisite quantity of zinc. But in preparing other varieties of sheet brass it is usual to employ crucibles heated in coke fires as described for cast brass. Gas- or oil-fired furnaces are also employed, and are coming steadily into favour. The crucibles generally hold about 120 lbs. of metal. In either case the alloy when melted is cast in iron moulds into flat bars, varying in size, but of which one about $4\frac{1}{2}$ in. \times $\frac{1}{2}$ in. \times 90 in. may be taken as an example. These are known as 'strips' and the operation is known as 'strip casting.'

The strips are then 'broken down' by being passed cold through a pair of rolls, the operation being repeated as often as the metal will allow. The work done upon the metal soon causes it to become hard, and if the rolling were continued the strip would readily develop cracks. To obviate this the metal is annealed at a red heat, about 650°C., and the surface is cleaned from oxide by pickling in dilute sulphuric acid. After washing with water, the operations of rolling, annealing, pickling, and washing are repeated, in order, until the desired shape and thickness are obtained. During the process of rolling the original crystalline structure of the alloy is largely broken down and an amorphous hard matrix is produced. This subject has been fully dealt with by Beilby (*Hard and Soft States in Metals*, *J. Inst. of Metals*, 1911, 6, 5). On annealing, the first effect is to restore the crystalline structure of the alloys. At the same time it becomes soft and ductile. If, however, the temperature of annealing be too high, or the time unduly prolonged, the crystals increase in size, and ultimately become so large that the material is quite weak, brittle, and worthless for practical purposes. The proper annealing temperature varies with the composition of the alloy, and the whole question has been studied by Hudson and Bengough (*J. Inst. of Metals*, 4, 1910, 92), and by Bengough (*ibid.* 7, 1912). With 70-30 p.c. brass the best annealing temperature is between 600° and 700°, but brass may become coarsely crystallised or 'burnt' at 100° below the solidus line if maintained for sufficient time, while it may be safely heated to within a few degrees of the solidus if the time does not exceed half an hour. Annealing commences at a lower temperature with brass which has received much cold work; in such cases even 300°C. may produce a marked effect (Matthewson and Phillips, *Amer. Inst. Min. Engs.* Feb. 1916). As sheet brass is used for so many purposes, its composition varies over a wide range, extending in fact from a mere trace to 40 p.c. of zinc. Turner has shown (*Chem. News*, 63, 227, 64, 143) that the use of impure washing water containing chloride leads to the production of copper-red stains and smears, on the surface of the finished brass, which is a cause of frequent loss and trouble. The cause of red stains has been more fully studied by E. A. Bolton (*Inst. Metals J.* 30, 35), who concludes the copper oxide reacting with the pickle deposits copper and causes the stains.

Since the ductility of the alloy increases with the proportion of copper, alloys such as best red brass, gilding metal, and percussion-cap metal contain from 80 to 90 p.c. of copper. Dutch metal contains 80–85 p.c.; Prince's metal, 75 p.c.; best English sheet brass, 70–72 p.c.; ordinary, 66.6 p.c.; common, 63 p.c.; and yellow metal, 60 p.c. As already explained, this last alloy, though somewhat deficient in ductility, is strong and possesses the great advantage that it can be rolled either hot or cold. White metal alloys are used in the form of sheet to a limited extent, and these contain less than 50 p.c. of copper. The cheaper yellow alloys, rich in zinc, do not 'stand the fire' so well in soldering, and it is not usual to solder anything containing less than 60 p.c. copper. Even with this composition a special soft solder has to be employed, whilst red brass stands the fire best, and can be used with the hardest solder.

Brass wire is made from sheet brass, the sheet of suitable thickness being slit into thin strips by cutters, and the strips are then drawn into wire at the draw bench. The chief varieties of wire arranged in order of ductility are as follows:—Red metal, Prince's metal, ordinary, common, and yellow metal. The first two of these were formerly used in the button trade, as in soldering on the shanks with hard solder they 'stood the fire' well. The other varieties can all be soldered with suitable solder of low melting-point, but the difficulty of soldering increases with the proportion of zinc.

Brass tubes. There are two principal methods of producing brass tubes. By the original process, which is still largely employed, sheet brass of the required composition and thickness is cut into strips of the necessary length; the strips are then drawn through a die, which imparts a circular shape, and the edges are soldered together by the use of powdered solder and borax made into a cream with water. Small tubes are soldered by being drawn through a small furnace fired with small coal or coke, but large tubes are now generally united by the use of a gas blowpipe, which gives a local and easily regulated heat. In the second and more modern method of manufacture brass tubes are solid-drawn, and thus the operation of soldering is dispensed with. This process is chiefly employed for large tubes and for tubes of special quality, as the soldered joint in tubes made in the ordinary way is always more brittle than the rest of the material. The soldered joint is also frequently a cause of corrosion in tubes exposed to steam or salt water. For solid-drawn brass tubes a short hollow cylinder of metal is cast in suitable moulds, and by drawing on a mandril, with frequent annealings, this hollow cylinder is gradually elongated to the required dimensions.

Condenser tubes are generally made of 70 p.c. copper, 30 p.c. zinc; or, according to the Admiralty specification, in which 1 p.c. of the zinc is replaced by tin. The corrosion of condenser tubes is a source of considerable loss and trouble, especially in the mercantile marine. The causes which lead to such corrosion have been studied by Brühl (*J. Inst. of Metals*, 6, 279) and by Bengough (*ibid.* 1911, 5, 28, and in a series of later reports to the Corrosion Committee of the Institute of Metals).

Ornamental patterns on brass tubes when parallel with the length of the tube are produced by passing the plain tubes through a set of suitably arranged rolls, on the surface of which the desired pattern is cut. But when the pattern is of a spiral form it is usual to draw the plain tube through a die of the requisite shape, arrangements being made for either the tube or the die to rotate during the operation. Best drawn tubes for locomotives and similar purposes contain 70–72 p.c. of copper; the composition of other tubes varies according to the quality of the sheet brass used in the process of manufacture.

Colouring of brass. A considerable proportion of the goods originally made of brass are so coloured before passing into commerce that the tint of the metal itself is no longer to be recognised. The most important applications of colouring are the following:—Bronzing in various shades, such as black, grey, red, green, &c.; lacquering in many shades; and bright colouring with highly coloured, transparent lacquers. These processes of colouring may be divided into two classes according as to whether they are conducted before or during the operation of lacquering.

As has been pointed out by Löwenherz, a variety of shades of colour can be obtained by carefully heating bright clean brass to definite and regulated temperatures. These colours so produced are formed in the following order:

- | | |
|-------------------------|---------------------|
| 1. Orange yellow. | 6. Rose-red gold. |
| 2. Clear golden yellow. | 7. Violet-rose red. |
| 3. Orange gold. | 8. Clear rose. |
| 4. Dark gold. | 9. Steel white. |
| 5. Brown gold. | |

Some of the colours are of great firmness and beauty, and the process is full of promise for special purposes, but has not hitherto been successfully adopted on any considerable scale.

The methods of bronzing, applied before lacquering, include the following:

Copper bronzing.—To develop a copper-coloured surface on brass the metal may be cautiously rubbed with hydrochloric acid, or, still better, it may be immersed in a slightly acid dilute solution of copper nitrate until the desired depth of colour is obtained. To produce a dark copper-bronze colour, treat as above, and blacken the surface with plumbago before lacquering.

Grey bronze.—A cheap grey bronze is produced by rubbing with plumbago and using a nearly colourless lacquer. A more permanent grey bronze is produced by the use of a solution of arsenic trioxide in hydrochloric acid; the addition of iron salts improves the effect. For common work, which is *not soldered*, an aqueous solution of mercuric chloride rendered acid with vinegar is frequently used.

Black bronze.—The very beautiful and permanent black bronze used for mathematical and scientific instruments is produced by the application of a dilute aqueous solution of platinum tetrachloride which was introduced for this purpose about the year 1860.

Green bronze.—A cheap green bronze which was formerly much in favour was obtained by the use of plumbago followed by a transparent yellow lacquer.

Ordinary lacquer is a solution of shellac in proof spirit, but other gums and solvents are also used. A colourless 'dip' lacquer (i.e. one in which the articles may be dipped, instead of the lacquer being applied by means of a brush to the warm surface as usual) is made by dissolving nitrocellulose in amyl acetate. For ordinary purposes many shades of lacquer from colourless, through yellow, to brown are regularly employed. For the cheaper kinds of bronzing special bronze lacquers of a variety of colours are used; and in addition richly coloured transparent lacquers of numerous shades are produced for the manufacture of brightly coloured thin sheet metal for ornamental purposes. In this branch of manufacture the use of aniline derivatives has led to numerous improvements.

T. T.

COMPOUNDS OF ZINC.

Zinc oxide ZnO . This substance, the *nix alba*, 'philosophical wool,' or 'flowers of zinc' of the alchemists, the *tutia* or *pompholyx* of the ancients, occurs as the mineral zincite or red zinc ore which is a mixture of zinc oxide and 7-12 p.c. red manganese oxide. It is often found in red or orange-yellow hexagonal crystals or in granular masses. Zinc oxide is occasionally found crystalline in zinc and brass melting furnaces.

Zinc oxide is known in commerce as zinc white, and is generally prepared on the large scale by burning zinc or its ores in retorts, or in an electric furnace, the zinc fumes being led into chambers where they meet a current of air and the oxide thus formed is led into a second chamber and allowed to condense; or the ore may be heated with anthracite or charcoal, and the resulting hot fumes treated with air. The New Jersey Zinc Company, working on franklinite ore, a zinc-iron-manganese spinel, make the greater part of the zinc oxide on the American market. The ore is washed, crushed, and passed by a belt conveyor over a separating table where the franklinite is removed by an electro-magnet. This is mixed with coal and spread on grates through which air is blown. The reduced zinc is converted into oxide which is drawn by the aid of fans through cooling pipes into fabric bags which are tapped at the bottom from time to time (see Eng. Pats. 16129, 1891; 11233, 1894; 4310, 1894; 12274, 1901; 18015, 1903; 4058, 1904; 21787, 19339, 1906; U.S. Pat. 902280, 1908; Fr. Pat. 403681, 1909; amongst others; J. Soc. Chem. Ind. 1894, 401; *ibid.* 1901, 911; *ibid.* 1903, 1138; *ibid.* 1906, 1056; *ibid.* 1907, 1150; *ibid.* 1910, 88; Schnabel, Eng. and Mining J. 1892, 9, 26295).

Zinc oxide may also be prepared by heating zinc sulphate with carbon for about 2 hours at about 650° (Eng. Pat. 3906; D. R. P. 93315).

A hot solution of sodium sulphate or other alkali salt is electrolysed with zinc electrodes; zinc sulphate is formed at the anode, and sodium hydroxide at the cathode. These react forming zinc hydroxide, which is then calcined (Fr. Pats. 328491, 1903; 348294, 1904; U.S. Pat. 771025, 1903; Ind. Elektrochem., 1904, 8, 29).

The zinc oxide of pharmacy is prepared either by burning the metal or by precipitating very pure zinc sulphate with a hot solution of

sodium, magnesium, or other carbonate, and heating the dried carbonate to expel carbon dioxide (Jansen, Mag. Pharm. 26, 74; Dulk, Berl. Jahrb. Pharm. 24, 2, 74; 29, i. 59; D. R. PP. 21987, 151022; Rigg, Eng. Min. J. 75, 626).

Crystalline zinc oxide of sp.gr. 5.782 may be obtained by heating the nitrate (Brügelmann, Zeitsch. anal. Chem. 29, 126); by heating zinc chloride in a stream of water vapour (Daubrée, Compt. rend. 1854, 39, 153); and by a number of other methods (Sidot, *ibid.* 1869, 69, 202; Goigou, *ibid.* 1887, 104, 120).

A large number of patents have been taken out for the preparation of the oxide by various methods, of which the following may be mentioned: Fr. Pats. 338977, 1903; 373027, 373953, 1906; 406150, 1908; 404840, 1909; 412214, 411672, 1920; Eng. Pats. 2532, 1905; 24526, 1906; U.S. Pats. 815516, 1906; 849322, 900088, 1908; 919375, 919376, 920336, 921909; J. Soc. Chem. Ind. 1897, 182; 1033; 1904, 1034; 1906, 325, 374; 1907, 1910, 233, 425, 1016.

Zinc oxide is a white powder of sp.gr. 5.6 (see Fuchs and Schiff, *ibid.* 1896, 363), which, on heating, becomes lemon-yellow, but on cooling again becomes white.

According to Schüpphaus, the yellow colour is due to the formation of a suboxide (*ibid.* 1899, 987). Zinc oxide volatilises in the electric furnace, the vapours condensing in long, transparent crystals (Moissan, Compt. rend. 1892, 115, 1034). In a current of air it commences to volatilise at 1100° (Doeltz, Metallurgie, 1906, 3, 212). At a bright red heat the oxide is probably polymerised to some extent (de Forcrand, Compt. rend. 1902, 134, 1426; *ibid.* 135, 36; Ann. Chim. Phys. 1902, [vii.] 27, 26). Water dissolves about 0.003 grm. per litre (Remy and Kuhlmann, Zeitsch. anal. Chem. 1924, 65, 161). Zinc oxide commences to be reduced by carbon in an atmosphere of nitrogen at 800°, by carbon dioxide at 600°, reduction in both cases increasing rapidly with rise in temperature (Doeltz and Graumann, Metallurgie, 1907, 4, 290). By magnesium it is reduced with explosive violence (Winkler, Ber. 1890, 23, 120). It may be reduced on heating it in dry hydrogen.

The reaction between zinc oxide and carbon monoxide has been examined by passing a stream of gas over the heated oxide in a quartz boat and determining the carbon dioxide in the issuing gases and the amount of zinc reduced by the loss in weight of the zinc oxide boat due to volatilisation of the metal. The velocity of the reaction $\text{ZnO} + \text{CO} = \text{Zn} + \text{CO}_2$ is very small at 420°, but increases rapidly with rise of temperature. At the same time the relative proportion of carbon dioxide formed increases owing to decomposition of the carbon monoxide into dioxide and free carbon. On the other hand, especially on cooling to temperatures below those at which reduction of the zinc oxide takes place, a certain amount of carbon dioxide becomes reduced again to monoxide by the metallic zinc formed in the early stages. Above 700° no further deposition of carbon takes place, showing that carbon is no longer in equilibrium with the products of the reaction. The proportion of zinc reduced depends not on the quantity of carbon monoxide passing through the apparatus, but on the time

of contact. Experiments on the reduction of zinc oxide by carbon showed that the presence of small quantities of oxygen accelerates the reaction considerably; in the total absence of oxygen a temperature of over 1000° is necessary in order to obtain any dissociation of zinc oxide in the presence of carbon. It therefore appears that the reduction of zinc oxide by carbon takes place, under commercial conditions, through the intermediate action of carbon monoxide (A. d'Hooghe, Bull. Acad. roy. Belg. Cl. Sci. 1923, 9, 323; Chem. Zentr. 1924, 95, 1; J. Soc. Chem. Ind. 1924, 43, B. 260).

When strongly heated in the oxyhydrogen flame it emits an intense white light, and is seen to phosphoresce when cooled in the dark. The character of the light emitted by incandescent zinc oxide has been examined by E. L. Nichol and B. W. Snow (Phil. Mag. [v.] 32, 420; and [5] 33, 19; see also Schmidt, Ann. Physik. 1904 [iv.] 13, 622; Tafel, *ibid.* 14, 206), who have studied the behaviour of zinc oxide under the action of canal rays.

Certain preparations of zinc oxide when illuminated with ultra-violet rays become luminous, the luminescence slowly increasing in intensity to a maximum and on removing the exciting rays immediately disappears. A weak and transient phosphorescence is shown at the same time (Winther, Zeitsch. wiss. Photochem. 1921, 21, 45).

One part of the oxide dissolves in 230 parts of water (Dupré and Bialas, Zeitsch. angew. Chem. 1903, 16, 54). If quite pure it dissolves completely in ammonia. It is readily soluble in acids, forming the corresponding zinc salts which are colourless substances having a disagreeable taste, are often poisonous to plants and animals, act as emetics, and are employed in medicine, chiefly for external application.

Zinc white has been recommended as a useful, efficient, and more healthy substitute for white lead for oil painting, and in the preparation of varnishes (Livache, Compt. rend. 1901, 132, 1230; Bull. Soc. d'Encouragement, 1908, 110, 516; 1902, 103, 690; Lenoble, J. Soc. Chem. Ind. 1904, 829). For this purpose zinc white, alone, or mixed with finely-ground silica and calcium carbonate, is made into an emulsion with linseed or a similar oil (Eng. Pat. 4870, 1893; Fr. Pat. 366465, 1906; D. R. P. 175402, 178983; J. Soc. Chem. Ind. 1894, 22; *ibid.* 1906, 1056).

Many fast colouring matters, inorganic and organic, are, however, bleached by light when mixed with zinc oxide and gum, especially in glass. White lead and cadmium yellow are blackened by light when mixed with zinc oxide and glycerol. Eosin and cyanin are more rapidly bleached in the presence of zinc oxide, fuchsin is not. The zinc oxide itself is chemically unchanged when acting as a photo-catalyst (Winther, Zeitsch. wiss. Photochem. 1922, 21, 141).

A mixture of zinc hydroxide and hydrocarbonate, used as a white pigment, is prepared by intimately pulverising zinc ore with quicklime, then extracting the mixture with liquid ammonia. After removing foreign metals by ordinary methods the ammoniacal liquid is distilled in a vacuum with or without the application of heat (Fr. Pats. 309079, 2001, 1903).

A mixture of ground zinc white and hydrated oxide of zinc precipitated in the cold or at 50° – 80° , is said to be a useful enamel pigment when used in the proportions represented by the formula $2\text{ZnO} + \text{Zn}(\text{OH})_2$, whilst for matt-surface paints the proportion should be $6\text{ZnO} + \text{Zn}(\text{OH})_2$. As a second coat for enamelling, zinc carbonate may be substituted for a part or the whole of the zinc oxide (Joannis, J. Soc. Chem. Ind. 1906, 486).

Zinc soaps are manufactured by thoroughly mixing about 0.25 p.c. oleic or other aliphatic acid with zinc oxide and a little water. The resulting zinc soap can now be mixed into an emulsion with raw or boiled oil, a thick paste thus being formed, the constituents of which do not separate even on prolonged standing (Fr. Pat. 368755, 1906).

Zinc lead pigment consists of zinc oxide and sulphate, lead oxide and sulphate, some sulphur dioxide and water (Buskett, Eng. and Ming. J. 1907, 83, 760).

Zinc oxide is used in the manufacture of cements (D. R. P. 56958; Fr. Pats. 332788, 333671, 1903). When mixed with aluminium phosphate it is used as a dental cement (Grenet, Chem. Zeit. 1909, 33, 610).

It is also employed in the glass industry (J. 1894, 151, 354; Zschimmer, Chem. Zentr. 1907, ii. 1461; Walker, J. Amer. Chem. Soc. 1905, 27, 865); and in the preparation of crystalline glazes (Holdercroft, Trans. Eng. Ceramic Soc. 1909–10, 9, 37).

Crystalline zinc glazes are formed by the separation of zinc silicate on slow cooling of the glaze. It has a smaller coefficient of expansion than other glazes, and when melted on to pottery or stone ware is less liable to 'craze' than lead glaze.

By addition of different oxides, characteristic colour effects can be obtained with zinc glazes. Zinc oxide may also be used in place of the more costly tin oxide for producing opalescent glazes (Petrik, Chem. Zeit. 1908, 32, Rep. 490).

Crystalline zinc glazes are prepared by mixing 27.389 parts by weight of zinc oxide with 7.382 potassium nitrate, 13.770 borax, 7.000 whiting, 4.466 flaky boric acid, 0.600 cupric oxide, and 39.693 flint. The glaze should be ground as finely as possible and applied to the surface to be glazed with dextrin as an adhesive (Riddle, Trans. Amer. Ceramic Soc. 1906, 8, 336; Minton, *ibid.* 1907, 9, 782). It is also used for the production of white and colour resists employed in printing processes (Leuber, Zeitsch. Farben. and Textil Ind. 1904, 3, 417); for the preparation of certain sizing materials (D. R. P. 194726; J. Soc. Chem. Ind. 1908, 634); and to some extent in analytical processes in the laboratory (Meineke, Zeitsch. angew. Chem. 1888, 252; Koninek, Chem. Zeit. 1906, 29, Rep. 5).

For the estimation of zinc oxide in zinc paints and lithopones, see J. Soc. Chem. Ind. 1907, 977; Stromeyer, Arch. Pharm. 27, 549.

Zinc grey is obtained as a by-product in the manufacture of zinc white. Made into a paste with wood oil it is used as a cement for steam joints (Livache, Bull. Soc. d'Encouragement, 1905, 107, 568). It also forms a good, silver-grey oil paint.

Zinc hydroxide $\text{Zn}(\text{OH})_2$ is obtained as a

white powder by adding caustic potash or soda or ammonia to a solution of a zinc salt. It may be obtained crystalline by allowing zinc to remain in contact with iron or copper under a layer of ammonia or by allowing its saturated solution in caustic potash to stand, or by the action of water on zinc oxide (de Forcrand, *l.c.*). It may be obtained in two different crystalline forms: thin needles or short thick rhombic crystals (Fricke, *Amer. J. Sci.* 1925, v. 9, 145). It is stable in air up to 85°, loses nearly all its water at 130°–140°, is readily soluble in excess of ammonia and alkalis towards which it behaves as a weak acid, H_2ZnO_2 (Herz, *Zeitsch. anorg. Chem.* 1901, 26, 90; Rubenbauer, *ibid.* 1902, 30, 331; Hantzsch, *ibid.* 289; Bonsdorff, *ibid.* 1904, 41, 132; Moir, *Chem. Soc. Proc.* 9105, 310; Dawson and McCrac, *Chem. Soc. Trans.* 1900, 1239; Euler, *Ber.* 1903, 36, 3400; Kuriloff, *Zeitsch. Elektrochem.* 1906, 12, 209; *Bull. Acad. St. Petersburg*, 1901, 1, 95). It has been supposed that the zinc hydroxide in alkaline solution is mainly present as a colloidal modification. It can exist as H_2ZnO_2 , and in two modifications of $Zn(OH)_2$, characterised by different solubilities, one variety forms regular crystals (Klein, *Zeitsch. anorg. Chem.* 1912, 74, 157). A mixture of zinc ammonium hydroxide and copper ammonium hydroxide has been used for pectinising cellulose and similar substances to produce a kind of vegetable parchment (*J. Soc. Chem. Ind.* 1904, 122).

Zinc peroxide ZnO_2 , also known under the trade names *Zinkonal*, *Dermogen*, *Ektogan*, and *Zinc perhydrol*, is formed by the action of hydrogen peroxide on zinc oxide or hydroxide, or on an ammoniacal solution of zinc nitrate. It may also be made by adding a solution of zinc sulphate in excess to a solution of sodium hydroxide containing hydrogen peroxide when the zinc is totally precipitated as hydroperoxide (Kuriloff, *J. Russ. Phys. Chem. Soc.* 1890, 22, 171; de Forcrand, *Compt. rend.* 1902, 134, 601; *ibid.* 135, 103; *D. R. P.* 171372; Kazaneky, *J. Russ. Phys. Chem. Soc.* 1910, 42, 1452; Carrasco, *Gazz. chim. ital.* 1911, 41, i. 16). It has also been formed by subjecting an aqueous solution of barium peroxide to the action of a zinc salt, the acid radicle of which forms a soluble salt with barium (*U.S. Pats.* 709086, 1902; 740832, 1903); or better, by the electrolysis of a zinc chloride solution contained in a vessel with a porous diaphragm, hydrogen peroxide being added to the cathode compartment and platinum or carbon being used as anodes and platinum or tin as cathodes (*D. R. P.* 151129; for another method, see *J. Soc. Chem. Ind.* 1905, 947; also *Fr. Pat.* 364825, 1906). A number of peroxides have been described, but, according to Kuriloff (*Compt. rend.* 1903, 137, 618; see also de Forcrand, *ibid.* 1904, 138, 129), the only one which is a definite chemical compound has the composition $ZnO_2 \cdot Zn(OH)_2$.

or

the others all being mixtures of varying quantities of zinc peroxide with zinc oxide or zinc hydroxide (Lemaire, *Rép. Pharm.* 1910, 22, 1; Hengeler and Philipp, *J. Soc. Chem. Ind.* 1906, 226; Ebler and Krause, *Zeitsch. anorg. Chem.*

71, 150; Riesenfeld and Nottebohm, *ibid.* 1911, 1915, 90, 150). According to Sjöström, (*ibid.* 1917, 100, 237) zinc perhydrate is not a simple chemical individual, since by trituration with water it can be separated into fractions containing varying quantities of active oxygen. It is to be regarded as a mixture of substances derived from the two compounds $Zn(OH)_2$ and

the hydroperoxides being of the types

Zinc peroxide is a yellowish-white, tasteless, odourless, non-hygroscopic antiseptic, non-irritant powder. It is stable in the autoclave to 130°, and at a dry heat to 150°, is insoluble in water, and gives all the ordinary reactions of a peroxide.

Mixed with tartaric acid it is applied as a dressing to wounds, chronic ulcers, &c. It thus liberates hydrogen peroxide *in situ*, and is therefore more active than the same quantity of the latter applied in the usual way. For eczema and other skin diseases it is applied mixed with half its weight of potassium iodide and some tartaric acid (*Chem. Zentr.* 1906, ii. 548; *D. R. PP.* 14821, 157737; Homeyer, *Apoth. Zeit.* 1902, 17, 697; *J. Soc. Chem. Ind.* 1905, 947).

Zinc chloride $ZnCl_2$, the *oleum lapidis calaminaris* of Glauber, who first described it in 1648, may be prepared in the anhydrous state by distilling zinc oxide with sal ammoniac, forming the 'butter of zinc' of Hellot; by distilling zinc with corrosive sublimate (Pott); by the action of chlorine on the metal (Westrumb), or by heating dehydrated zinc sulphate with calcium chloride (Persoz) (*Eng. Pats.* 982, 1892; 13813, 1895; *D. R. PP.* 154518, 158089).

On the large scale it is usually obtained by placing scrap zinc in a stone, cast iron, or wooden vessel containing hydrochloric acid. The solution is neutralised with sodium carbonate, warmed to 40° or 50°, and mixed with bleaching powder to precipitate iron and manganese. The clear zinc chloride solution is siphoned off and boiled down in enamelled iron pots. The evaporation is continued until the temperature of the liquor is 230° or 240°, a little potassium chlorate is added to oxidise any organic matter, and some pure hydrochloric acid carefully poured into the hot solution to dissolve any basic salt. The mass is then allowed to solidify, the agitation being kept up all the time, and while still warm it is packed in iron drums of 30–50 kilos. capacity, which are at once closed air-tight.

According to a more recent patent (*Fr. Pat.* 385448, 1907), zinc-heating material is intimately mixed with sawdust or similar substance containing cellulose in earthenware or cast-iron twin tubular retorts, which are used alternately. The first retort is heated to 120°–180°, and chlorine is passed in at the base, hydrochloric acid is thus generated *in situ*, and the temperature rises spontaneously to 230°–250°. The products of combustion pass from the upper part of the retort to a receptacle where the tar is deposited and thence to the base of the second retort where the excess chlorine is fixed and the products then pass out into a second receptacle,

where the tar is again fixed, and thence into a coil and receiver cooled by water. The mass thus obtained is lixiviated with water. Iron and manganese are then oxidised with chlorine and calcium hypochlorite, the iron is precipitated by zinc oxide, the manganese, if necessary, by lead peroxide (D. R. P. 154085; 136521), and the other metals by agitation with zinc. The remaining liquor is then finally evaporated to obtain pure zinc chloride.

It may also be obtained almost pure by treating zinc compounds with ferrous chloride (D. R. P. 136521); by heating zinc ore to 550° passing hydrogen chloride over it, and finally lixiviating the mass so obtained (D. R. P. 158087). A large number of patents exist for the preparation and purification of zinc chloride by the above and other methods (Eng. Pat. 22826, 22827, 1894; 5662, 8449, 7561, 1895; 24573, 1896; 19878, 1900; D. R. P. 155066; 172460; U.S. Pat. 845868, 1907; 883426; 1908; Mallet and Guye, Chem. Zeit. 1904, 28; 763; J. Soc. Chem. Ind. 1893, 276; *ibid.* 1896, 450, 595; *ibid.* 1896, 198, 356; *ibid.* 1897, 1015; *ibid.* 1900, 146; *ibid.* 1905, 497).

Pure anhydrous zinc chloride can be prepared by dissolving 40 grms. of the chloride in 20 c.c. of hydrochloric acid (sp.gr. 1.19), an evaporating the solution in a tube of refractor glass through which a stream of hydrogen chloride is passed. The temperature is gradually raised, and after some time the mass solidifies with evolution of hydrogen chloride. The solid chloride is fused again rapidly in a current of the same gas. The dehydration is complete in 75 mins. (Grünauer, Zeitsch. anorg. Chem. 1904, 39, 389; see Vogel, Faraday Soc. Trans. 1906, May 5; see also D. R. P. 120970).

Zinc chloride is a white or greyish-white mass or powder, of sp.gr. 2.907 at 25°/4° (Baxter and Lamb, Amer. Chem. J. 1904, 31, 229). Its m.p. is variously given as 100° (Davy), 210° (Lorenz), 262° (Braun, Mylius, and Dietz), 290°–300° (Schulze). According to Grünauer the completely anhydrous chloride has m.p. 300°. It is very hygroscopic and deliquescent, odorless, poisonous, with a metallic astringent taste. It melts to a clear, mobile, highly refractive liquid, b.p. 730°–732°; in a current of chlorine it sublimes, forming acicular crystals. It forms hydrates with 1, 1.5, 2.5, 3, and 4 molecules of water (Dietz, Ber. 1899, 32, 90; Mylius and Dietz, *ibid.* 1905, 38, 921) and is probably monomeric or less hydrolysed in solution. Its aqueous solution dissolves paper and cotton, and it should therefore be filtered through asbestos or glass, not paper. When evaporated or boiled with zinc oxide, oxychlorides are formed (Perrot, Bull. Soc. chim. 1895, [iii.] 13, 975; Driot, Compt. rend. 1910, 150, 426), whilst if a solution of sp.gr. 1.7 be boiled with an excess of zinc oxide, the resulting liquid dissolves silk, and can be employed for separating the latter from wool, cotton, or linen. Zinc oxychloride is sometimes also used in the preparation of some dental cements, and as a pigment.

When zinc chloride is electrolysed, chlorine is evolved and crystalline zinc is deposited (Sapozhnikoff, J. Russ. Phys. Chem. Soc. 1905, 37, 153; see also Schultze, Zeitsch. anorg. Chem. 1899, 20, 323; Grünauer, l.c.).

form of rods or tablets. It is a powerful caustic, distinguished by its property of burning deeply and not spreading sideways. It is applied in substance, or made into a paste with starch or gypsum, to cancers, sloughing or unhealthy sores, and nævi (Lauder Brunton).

In dilute solution it is also used as an astringent, an antiseptic, a disinfectant, and as a deodorant.

A solution of zinc chloride, in the proportion of 1 lb. of the salt to 5 gallons of water, was patented by Sir W. Burnett (Eng. Pat. 7747, 1838) for the preservation of timber, and such a solution is still occasionally used for disinfecting and deodorising.

For the preservation of wood it has been recommended to employ an emulsion of aqueous zinc chloride, and wood-tar oil (D. R. P. 139441, 152179; Chem. Zentr. 1903, i. 749; *ibid.* 1904, ii. 379); or a 15 p.c. solution of a mixture of ammonium sulphate and a soluble zinc salt (D. R. P. 109324).

Zinc chloride is employed for weighting cotton goods (Furth, Färber Zeit. 1901, 12, 1; D. R. P. 214372, 215702; Chem. Zentr. 1900, ii. 1509, 1905), and for crimping cotton, wool, and silk (Bull. Soc. Ind. Mulhouse, 1898, 68, 350, 348; see also Flintoff, J. Soc. Dyers, 1896, 15, 151).

Solutions of zinc chloride were also employed by Mercer for treating cotton in the operation of 'mercerising' (v. CELLULOSE).

Zinc chloride is of considerable use as a condensing agent in many organic reactions, its reactivity being probably due to its tendency to form additive compounds which act catalytically.

Zinc chloride dissolves casein and these solutions have been employed for preparing artificial silk and hair. Zinc chloride has also been used in the production of hydrochloric acid from hydrogen and chlorine (Fr. Pat. 352419; Chem. Zeit. 1905, 29, 993); for the prevention of the rusting of iron (Reed, Trans. Amer. Electrochem. Soc. 1903, 3, 149); in the preparation of glass etching liquids (J. 1894, 354), and in the laboratory as an analytical, dehydrating and condensing agent and in the synthesis of a large number of organic compounds (Kondakoff, J. Russ. Phys. Chem. Soc. 1892, 24, 114, 309; J. pr. Chem. [u.] 48, 467; Dott, Pharm. J. 1905, [iv.] 21, 136; among others).

Primary alcohols are found to react readily with concentrated hydrogen chloride solution in presence of zinc chloride. This seems to indicate that the rôle of zinc chloride in reactions of this type is not that of a dehydrating agent, but of a catalyst operating by means of the formation of a molecular compound with the alcohol (J. F. Norris, Ind. Eng. Chem. 1924, 16, 184; Chem. Soc. Abstr. 1924, 126, i. 381).

By the gradual addition of zinc to fused zinc chloride until it ceases to be dissolved zincos-zinc chloride $\text{ZnCl}_2 \cdot 2\text{ZnCl}_2$ is obtained as a bluish-white hygroscopic solid.

Zinc chloride forms double chlorides with the alkali and other metals (Wells and Campbell, Zeitsch. anorg. Chem. 1894, 5, 273; Ephraïm, *ibid.* 1908, 59, 756; Ephraïm and Model, *ibid.* 1910, 67, 376, 379; Baxter and Lamb, l.c.; Gewecke, Annalen, 1909, 366, 217), with copper oxide (Mailhe, Compt. rend. 1901, 133, 226), an iodo chloride $\text{ZnCl}_2 \cdot 2\text{ICl}_2 \cdot 8\text{H}_2\text{O}$ (Weinland and

Schlegelmilch, *Zeitsch. anorg. Chem.* 1902, 30, 134), a *chlorobromate* (Löwenthal, *ibid.* 1894, 6, 355), and a *chloroborate* $6\text{ZnO} \cdot 8\text{B}_2\text{O}_3 \cdot \text{ZnCl}_2$ (Rousseau and Allaire, *Compt. rend.* 1894, 118, 1255). Zinc chloride also forms double compounds with ammonia, such as $\text{ZnCl}_2 \cdot \text{NH}_3$, $\text{ZnCl}_2 \cdot 2\text{NH}_3$ (Thoms, *Chem. Zentr.* 1889, ii, 965; Kwasnick, *Arch. Pharm.* 229, 310; Jaeger, *Ber.* 1902, 35, 3405), and with ammonium chloride (Curtius and Schrader, *J. pr. Chem.* 1894, [ii.] 50, 311; Meerburg, *Zeitsch. anorg. Chem.* 1903, 37, 199).

A solution of zinc ammonium chloride is used in soldering for the purpose of removing oxide from the surface of the metals.

Zinc perchlorate $\text{Zn}(\text{ClO}_4)_2$ may be obtained by dissolving the metal, its oxide, or carbonate in aqueous perchloric acid. The salt crystallises with 4 and 6 mols. of water, and is highly hygroscopic. When heated it decomposes before all the water is expelled, so that the anhydrous perchlorate cannot exist. The water in the hexahydrate may be replaced by ammonia. The ammoniated perchlorate is liable to explode when heated.

Zinc bromide ZnBr_2 is readily made by digesting granulated zinc with bromine water. It resembles the chloride, and is used to a small extent in medicine in the treatment of epilepsy.

In the absence of moisture zinc reacts with a mixture of ethylene dibromide, or ethylene di-iodide, and acetone to give the zinc halide with acetone of crystallisation. At the commencement of the reaction ethylene is evolved.

Zinc bromide-acetone, $2\text{ZnBr}_2 \cdot 3\text{C}_2\text{H}_5\text{O}$, colourless needles, m.p. $32^\circ\text{--}34^\circ$, is easily soluble in water, with slow deposition of zinc hydroxide. **Zinc iodide-acetone**, $\text{ZnI}_2 \cdot 2\text{C}_2\text{H}_5\text{O}$, pale yellow, elongated prisms, m.p. $45^\circ\text{--}47^\circ$, is deliquescent and slowly decomposed by water (I. Coucoulesco, *Bul. Soc. Chim. Romania*, 1924, 6, 36; *Chem. Soc. Abstr.* 1924, 126, ii, 411).

Zinc iodide ZnI_2 is also employed in medicine, as an application to enlarged tonsils and in the form of ointment to reduce swellings. It is also administered internally in cases of scrofula, chorea, and hysteria. It has found a limited application in photography.

For a number of double compounds of the bromide and iodide with other metallic compounds, see Ephraim, *l.c.*; Ephraim and Model, *l.c.*; Rousseau and Allaire, *Compt. rend.* 1893, 116, 1445; *ibid.* 119, 71; Tassiliy, *ibid.* 1896, 123, 323; Dubois, *ibid.* 1903, 143, 40; Chrétien, *Ann. Chim.* 1898, [vii.] 15, 358; Mosnier, *ibid.* 1897, [vii.] 374.

Zinc fluoride ZnF_2 is formed by the action of hydrofluoric acid on zinc or on zinc oxide at a red heat, or on zinc chloride at $800^\circ\text{--}900^\circ$ (Poulesco, *Compt. rend.* 1893, 116, 581). It forms slender, colourless, transparent needles, sp.gr. 4.84 at 15° , sparingly soluble in cold water, soluble in boiling mineral acids. It is reduced by hydrogen at a red heat; when heated in air it forms zinc oxide. When dissolved in hydrofluoric acid, or when zinc is dissolved in excess of hydrofluoric acid, it forms the compound $\text{ZnF}_2 \cdot \text{HF}$, which has been recommended for use in the preservation of wood, particularly of telegraph poles (Nowotny, *Chem. Zentr.* 1906, ii, 355). Like the other halides, zinc fluoride

yields a number of double salts (Helmolt, *Zeitsch. anorg. Chem.* 1893, 3, 115; Weinland and Köppen, *ibid.* 1899, 22, 286; Georgia, *Gazz. chim. ital.* 22, i, 55; Higley, *J. Amer. Chem. Soc.* 1904, 26, 613; Rimbach and Kilian, *Annalen*, 1909, 368, 101).

The electrolysis of fused anhydrous zinc fluoride or a fused mixture of the fluoride and sodium chloride has been recommended as a mode of making electrolytic zinc (Gallo, *Gazz. chim. ital.* 1913, 43, i, 361).

Zinc sulphate ZnSO_4 . This salt has long been known under the name which it still bears, of 'white vitriol.' It was obtained, on a manufacturing scale, as far back as the sixteenth century, by lixiviating roasted zinc sulphide by means of water, and crystallising the solution—a method still practised, with certain modifications (U.S. Pat. 851639, 1907; *J. Soc. Chem. Ind.* 1907, 608).

In some processes the zinc pyrites is previously treated with sulphuric acid, after which it is roasted (D. R. P. 154518). It is then sometimes further treated with oxidising agents. In some cases again the ore is treated with a mixture of dilute sulphuric acid, ferrous sulphate, and a little sodium chloride (D. R. P. 197044), or with ferric sulphate alone (D. R. P. 200613). According to D. R. P. 135056, after converting the sulphide ore into the sulphate in the ordinary way, the product is roasted with calcium hydroxide and sodium nitrate in a muffle furnace in order to drive off the impurities, or to convert them into insoluble compounds. When the process is finished, the zinc sulphate is lixiviated out (see also D. R. P. 120822, 135182; Knokloch, *Pharm. Zeit.* 40, 472; Hofmann, *Amer. Inst. Mining Eng. Trans.* 1905, 117; *Fr. Pat.* 384904, 1907).

Native zinc sulphate or *goslarite* is occasionally found in zinc mines, being probably formed by the oxidation of zinc sulphide.

Zinc sulphate separates from its solution at the ordinary temperature in right rhombic prisms, isomorphous with magnesium sulphate, and of the composition $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$; sp.gr. 1.95; 2.036 (Mohs). It has a strong metallic styptic taste, and effloresces slightly in dry air. According to Poggiale, 100 parts of water dissolve the following amounts of zinc sulphate at different temperatures (see also Callendar and Barnes, *J. Phys. Chem.* 1897, 2, 536, who give slightly different figures):—

	$\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$	Anhydrous salt
10°	138.2	48.3
20°	161.5	53.1
30°	191.0	58.5
50°	263.8	68.7
100°	653.6	95.6

The solubility of the hexahydrate and of the heptahydrate has been determined by Bury (*Chem. Soc. Trans.* 1924, 125, 2538), and Cohn and Hettenschij (*Zeitsch. physikal. Chem.* 1925, 115, 440).

The solution has an acid reaction and is poisonous. The salt is insoluble in absolute alcohol.

Solutions of zinc sulphate keep clearer in the light than in dark (Verda, *Chem. Zentr.* 1907, i, 1392).

A hexahydrated salt $\text{ZnSO}_4 \cdot 6\text{H}_2\text{O}$ is obtained

by crystallising the solution at 40°; sp. gr. 2.072 (Thorpe and Watts); a pentahydrated salt $\text{ZnSO}_4 \cdot 5\text{H}_2\text{O}$ by boiling the salt with alcohol (sp. gr. 0.825) (sp. gr. 2.206, Thorpe and Watts), and a dihydrated salt by pouring a cold saturated solution of zinc sulphate into strong sulphuric acid; and washing the precipitate with absolute alcohol until free from uncombined acid; sp. gr. 2.368 (Thorpe and Watts). The monohydrate salt is formed by heating the heptahydrated salt to 110° until it ceases to lose weight; sp. gr. 3.284 (Thorpe and Watts). The anhydrous salt is obtained by heating the heptahydrate to 300 sp. gr. 3.4. At a red heat all the sulphates are decomposed, yielding a residue of zinc oxide.

Zinc sulphate is used in dyeing and calico printing, in the manufacture of varnishes and drying oils for painting.

Coloured zinc pigments are prepared by intimately mixing together zinc sulphate with 6–30 p.c. of the sulphate of other metals which yield a coloured oxide, such as nickel, iron, cobalt, or manganese. The mixture is dried, finely divided carbon is added, and the whole is heated carefully at 650°. To produce a more delicately-tinted pigment, the zinc sulphate should first be purified by stirring zinc oxide into its solution and passing a current of chlorine through it, whereby the impurities are thrown down (Eng. Pat. 17031, 1896; Fr. Pat. 36657, 1908; J. Soc. Chem. Ind. 1903, 1074).

It is also used for the preparation of zinc white and other zinc compounds, and in pharmacy as an astringent, and in lotions, washes, and gargles. It is also occasionally employed as an emetic, and in the treatment of convulsive diseases. A number of basic sulphates, formed by digesting the oxide or hydroxide with strong solutions of zinc vitriol, or precipitating such solutions with varying quantities of potash, can be formed.

Zinc sulphate combines with ammonia and with other sulphates to form double salts (Curtius and Schrader, *l.c.*; Tröger and Evers, Arch. Pharm. 235, 644; Mallet, Chem. Soc. Trans. 1900, 77, 220; Tutton, *ibid.* 1905, 87, 23; Koppel, Zeitsch. physikal. Chem. 1905, 52, 85).

The compound $\text{ZnSO}_4 \cdot 3\text{H}_2\text{SO}_4$ has been separated from the acid in the first chamber in the manufacture of sulphuric acid from zinc blende (Hoffmann, Zeitsch. angew. Chem. 1910, 23, 1672).

Anhydrous zinc sulphate behaves towards alcohols as a mixed catalyst, its action being both dehydrating and dehydrogenating. The latter action preponderates as in the case of zinc oxide, and it is suggested that the sulphate may function as a basic salt. Its action is more marked than that of the oxide. A proportion of the aldehyde formed is condensed, but isobutylaldehyde and isovaleraldehyde may be obtained readily and in good yield, whilst glycerol yields acetaldehyde by internal dehydration. The action on acetone results in the formation of a small quantity of mesityl oxide and of phosgene (G. Brus, Bull. Soc. Chim. 1923, 33, 1433; Chem. Soc. Abstr. 1924, 128, i. 2).

According to Kolthoff and Verzyl (Rec. trav. chim. 1924, 43, 389) only potassium ferrocyanide is suitable for the potentiometric titration of zinc, the composition of the precipitate being $\text{K}_2\text{Zn}_2(\text{Fe}(\text{CN})_6)_3$. The addition of

a caesium salt causes the end point to be less sharp (cf. Treadwell and Chervet, J. Soc. Chem. Ind. 1922, 890 A). Ferrocyanides of sodium, magnesium, and calcium give with zinc salts a precipitate of zinc ferrocyanide, which forms a double salt with excess of the reagent. Barium ferrocyanide does not form a double salt with zinc ferrocyanide (J. Soc. Chem. Ind. 1924, 43, B. 539).

The results obtained by potentiometric titration of a zinc sulphate solution with M/40 potassium ferrocyanide at the ordinary temperature are about 1 p.c. too low, but substantially accurate results are obtained if considerable quantities of ammonium sulphate are added to the solution. The presence of large quantities of sodium, magnesium, calcium, and aluminium salts causes low results. Manganese, cadmium, and copper should not be present; ferric compounds are rendered harmless by addition of ammonium fluoride and sulphuric acid. The potassium ferrocyanide solution should contain 1 p.c. of ferricyanide. This renders it more sensitive to decomposition by light, but it can be kept indefinitely in vessels of dark brown glass (E. J. A. H. Verzyl and I. M. Kolthoff, Rec. trav. chim. 1924, 43, 380; J. Soc. Chem. Ind. 1924, 43, B. 539).

Zinc hydro- or hyposulphite ZnS_2O_4 is obtained by passing a current of sulphur dioxide into a mixture of zinc-dust and alcohol or water at a temperature above 40°. On stirring, a crystalline paste of the hydrosulphite is formed, which is washed with methylated spirits and dried *in vacuo* below 70° (Eng. Pat. 3811, 1907; D. R. P. 184564, 103403, 137494, 144281; Fr. Pat. 331095, 1903; Brunck, Annalen, 1903, 327, 240; Bazlen, Ber. 1905, 38, 1061).

Soluble double salts of zinc hydrosulphite with ammonium salts are obtained by the action of zinc-dust on alkali disulphite in the presence of acid and an ammonium salt (D. R. P. 203846, 1907).

Zinc hydrosulphite forms microscopic rhombic crystals, very soluble in water, giving, very readily, supersaturated solutions. It is employed as a reducing agent in the indigo dyeing industry.

Zinc sulphite ZnSO_3 is prepared by the action of sodium sulphite on zinc sulphate (Denigès, Bull. Soc. chim. 1892, [iii.] 7, 569). It forms a number of hydrates, double salts, and basic salts (Seubert, Arch. Pharm. 1891, 229, 316; Seubert and Elten, Zeitsch. anorg. Chem. 1893, 4, 61; Rammelsberg, Pogg. Ann. 67, 255).

It is used to a very limited extent in medicine.

Zinc sulphide ZnS , *ls. blende*, is one of the most important ores of zinc. Its value as an ore of zinc was first demonstrated by Brandt in 1735, it being formerly regarded as a worthless lead ore, *galena inanis*. It is found crystallised in forms derived from the regular system, usually of a red, brown, or black colour, due to the presence of foreign metals. Occasionally it is met with of a light yellow colour; sp. gr. 3.5–4.2. When heated under pressure (100–105 atm.) it fuses at 1800°–1900°. The solidified fused sulphide has a lustrous appearance and a bright greenish-yellow colour. It is the hexagonal modification (*wurtzite*). It occurs native in enantiomeric forms *α-ZnS* (*wurtzite*) and

β -ZnS (sphalerite), which become mutually transformed on heating.

It is obtained artificially as a white amorphous precipitate by adding an alkaline sulphide or sulphuretted hydrogen to a solution of a zinc salt (Eng. Pats. 396541, 25965, 1908).

In Schneider's method for the precipitation of zinc sulphide from feebly acid (sulphuric) solutions, proper neutralisation is a decisive factor for the success of the operation. The solution, to which a piece of Congo paper is added as indicator, should not be too dilute, it is made distinctly ammoniacal, acidified with sulphuric acid, then treated with strong ammonia solution, drop by drop, until the alkaline reaction persists after 5-10 seconds' stirring. The prescribed small excess of sulphuric acid, calculated on the subsequent dilution desired, is then added (O. Hackl, Chem. Zeit. 1924, 48, 326; Analyst, 1924, 49, 352).

A mixture of zinc sulphate (230 lbs.), water (90 gallons), ammonia of sp.gr. 0.91 (230 lbs.) is introduced into an enamelled digester and about 60 lbs. of carbon disulphide are added. The vessel is closed and heated to 100° with constant stirring, until the pressure is about 60 lbs. After 4 hours the pressure begins to fall, and in 10 hours it will have fallen to about 22 lbs., when the process is complete. The zinc sulphide is collected, washed, and dried. It is very finely divided and is suitable for use as a pigment (Eng. Pat. 11108, 1900).

Zinc sulphide is sometimes separated from its ores by immersing the crushed ore in a solution of sodium sulphate, disulphate, or nitrate, and skimming off the sulphide which rises to the surface (Eng. Pats. 26279, 1902; 27132, 1903; 20160, 20159, 1904; U.S. Pat. 780281; Fr. Pats. 326866, 326867, 1902). For other methods of preparing the sulphide, see Eng. Pat. 16272, 1902; Fr. Pats. 397631, 396541, 1908; 415605, 1910; D. R. PP. 132916, 137801, 149557, 167172, 167498, 171872, 179022).

It may also be obtained by dissolving zinc in an alkali hydroxide and then adding just sufficient alkali sulphide to precipitate the zinc (Fr. Pats. 353496, 353480); or by passing zinc chloride vapour over barium or stannous sulphide (Fr. Pat. 338322, 1903; Viard, Compt. rend. 1903, 136, 892). On exposure to light or by heating at 60° or 70° it is tinged light grey to light brown, especially when containing chlorides or sulphates of magnesium, calcium, or zinc. The darkening of zinc sulphide is due to the formation of free zinc. In order that a specimen should be sensitive to light, it must be phosphorescent and hygroscopic; it is more sensitive the more these conditions are satisfied. The darkening is due to the following series of changes. The preparation of the sulphide, involving ignition, affords a metastable product. Incident radiation raises the metastable molecules to a critical state, and, if the sample be dry, it simply emits radiation and reverts to the previous, metastable, condition. When, however, it has deliquesced slightly, hydrolysis occurs, producing hydrogen sulphide and zinc hydroxide. During illumination, a critical molecule of the sulphide reacts with the hydroxide, giving zinc and sulphurous acid, which with hydrogen sulphide affords sulphur, zinc pentathionate also being produced. The main

products are thus zinc and sulphur (André Job and Guy Emachwiller, Compt. rend. 1923, 177, 313-316; J. Chem. Soc. 1923, 124, ii. 600).

Zinc sulphide prepared by precipitation did not darken under any conditions of illumination. Ignited zinc sulphide, freed from materials with which it had been heated, showed a sensitiveness towards light from a quartz mercury lamp when the temperature of ignition was so high that measurable quantities of wurtzite were formed. The zinc blonde form of zinc sulphide was not affected by ultra-violet light from a quartz mercury lamp. The presence of small quantities of heavy metals made no change in the action of light in these cases. Crystallised zinc sulphide containing halogen compounds was sensitive to the long wave-length ultra-violet and the presence of small quantities of heavy metals intensified the action. The sensitiveness of zinc sulphide containing halogens was removed by washing the material, so far as the long wave-length ultra-violet was concerned, but this had no effect on the short wave-length ultra-violet effect or on the phosphorescence. Sensitiveness to long wave-length ultra-violet light was apparently induced by fusing zinc sulphide (wurtzite) with a halogen salt (M. Herter and W. Kordatzki, Zeitsch. physikal. Chem. 1923, 106, 386; J. Soc. Chem. Ind. 1924, 42, 1233 A).

E. Maas and R. Kempf have examined the various hypotheses put forward to explain the blackening of zinc sulphide, and discuss them in the light of their own and other experiments. They conclude that the phenomenon is due to the zinc sulphide forming zinc disulphide and finely divided metallic zinc on the surface of the mass. The mechanism of the process, they consider, is the same as that referred by Fajans to the action of light on silver bromide (Chem. Zeit. 1922, 46, 910). The ultra-violet rays in the light cause the transference of an electron from a negatively charged sulphur ion on the surface of the crystal lattice of zinc sulphide to a neighbouring positively charged zinc ion, whereby free uncharged atoms of zinc and sulphur are formed. The zinc appears as finely divided metal, the sulphur atom combines with neighbouring zinc and sulphur ions to form zinc disulphide. Amorphous freshly precipitated zinc sulphide not possessing a lattice structure is not sensitive to light; neither is zinc sulphide which has been ground in a mortar, since here the lattice arrangement has been disturbed. Blackened lithopone brightens in the dark, owing to oxidation of the metallic zinc, for it remains black if no oxygen is present (E. Maas and R. Kempf, Zeitsch. angew. Chem. 1923, 36, 293; J. Chem. Soc. Abstr. July, 1923, p. 491). According to A. Job and G. Emachwiller (Compt. rend. 1923, 177, 313-316) the darkening of zinc sulphide under the influence of light is dependent on the phosphorescence and hygroscopicity of a sample, and is due to the formation of zinc and sulphur. Hydrogen and zinc pentathionate are also formed, hydrogen sulphide being an intermediate product (cf. J. Chem. Soc. 1923, ii. 600; J. Chem. Soc. Ind. 1923, xlii. 896 A).

Zinc sulphide is soluble in dilute mineral acids, but is insoluble in acetic acid. When heated in a stream of sulphuretted hydrogen,

or in an electric furnace, it forms hexagonal crystals identical in form with the naturally occurring variety known as *wurtzite* (Mourlot, Compt. rend. 1896, 123, 45; Traube, Jahrb. Min. 9, 147). This is also formed when zinc oxide is heated in sulphuretted hydrogen. For other methods of converting the amorphous sulphide into the crystalline variety, see Villiers, Compt. rend. 1895, 120, 97, 149, 322, 498; Viard *ibid.* l.c.; Spring, Zeitsch. physikal. Chem. 1895, 18, 553; Staněk, Zeitsch. anorg. Chem. 1898, 17, 124.

Pure zinc sulphide melts at 1600°–1700° forming a light greenish-yellow lustrous mass and is distinctly volatile at higher temperature (Friedrich, Metallurgie, 1908, 5, 114). According to Krutwig (J. Soc. Chem. Ind. 1906, 267 the precipitated sulphide decomposes much more readily than natural zinc blende. Heated in a current of carbon dioxide it is readily decomposed at 1000° according to the equation $\text{ZnS} + 3\text{CO}_2 = \text{ZnO} + \text{SO}_2 + 3\text{CO}$. When treated with hot concentrated sulphuric acid, zinc sulphide evolves sulphur dioxide, whilst with the cold dilute acid, sulphuretted hydrogen is formed (Berthelot, Ann. Chim. 1898, [v.] 14, 176). Zinc sulphide may be completely reduced by heating it with spongy metallic iron at 1300° (Graumann, Metallurgie, 1907, 4, 6). Freshly precipitated zinc sulphide dissolves in potassium cyanide forming a double salt which is precipitated on boiling (Berthelot, Compt. rend. 1890, 128, 711).

When zinc sulphide is heated with carbon in nitrogen at 1300–1400°, a volatile compound is formed, which, if the containing vessel is of quartz, reacts with the silicon forming a volatile compound ZnSSi , which may also be obtained by heating zinc sulphide with silicon at 1300°. The compound ZnSSi forms hard brown crystals of homogeneous structure. It may be polished like a metal, has an electrical conductivity less than silicon, reacts with acids forming sulphuretted hydrogen and with alkalis with evolution of hydrogen (Fraenkel, Metallurgie, 1909, 6, 62).

Natural zinc sulphide crystals have the property of phosphorescing after exposure to light (Mourel, Compt. rend. 1890, 128, 57; Verneuil, *ibid.* 1888, 106, 1104), and the phosphorescent sulphide may be prepared artificially by heating precipitated zinc sulphide to redness in the presence of alkali chlorides or the sulphides of other metals (Eng. Pat. 385096, 1907; D. P. 163648; Henry, Compt. rend. 1892, 115, 35; Grüne, Ber. 1904, 37, 3076; Hofmann and D. P. 163648; Jorissen and Ringer, *ibid.* 1903, 33; Chem. Zentr. 1906, i. 644; see also D. P. 200998). The various factors which are concerned in the production of phosphorescent sulphide have been studied by MacDermott, Stewart and Wright (Chem. Soc. Trans. 1911, 663). The main results are as follows: Pure zinc sulphide prepared in various ways can be obtained in a phosphorescent condition. The addition of certain impurities has a marked effect in some cases, and this effect may take the form of inhibiting the phosphorescence (as with iron) or altering its tint (as is the case with manganese). The presence of a chloride, whether it be zinc chloride or the chloride of some other element, has an advantageous influence. The factor which has the greatest

influence is the temperature to which the zinc sulphide is heated. This temperature effect can be varied within limits; thus a sample heated for a very short time to a high temperature will give effects similar to those observed in another sample heated for a longer time at a lower temperature, provided that the lower temperature is not less than about 750°. Washing, rubbing, or disturbing the final product in any way tends to diminish its phosphorescent power. Exposure to ultra-violet light also decreases it (Loeb and Schmiedeskamp). Amorphous sulphide does not phosphoresce, nor does purely crystalline sulphide show such good phosphorescence phenomena as samples which contain semi-crystalline material. Specimens made from zinc salts not containing chlorides do not show such brilliant phosphorescence as those produced in the presence of chlorides (l.c. p. 681). With respect to the colour, most impurities influence the phosphorescence tint only slightly, the range of colours extending from lemon tint to green and bluish-green; but in the case of manganese the emitted light is golden to orange (cf. Tiede and Schleede, Ber. 1920, 53, [B.] 1721; 1923, 56, 674). The wurtzite and sphalerite forms of zinc sulphide prepared by heating the precipitated sulphide are both phosphorescent. The phosphorescence of the wurtzite form is the more persistent, but in both cases the decrease of luminous intensity is extremely rapid. Under the influence of heat and shock the two varieties are very thermoluminescent and triboluminescent (Guntz, Compt. rend. 1922, 174, 1356).

Schmidt has described the preparation of highly phosphorescent zinc sulphide, and has been drawn to the conclusion that its phosphorescence is inhibited by the presence of metals which yield black sulphides. This observation is directly opposed to the observations of Tomaschek (A. 1921, ii. 588). It is pointed out that Schmidt's procedure does not give any guarantee that the necessary amounts of copper are not introduced with the many salts employed, and that it is therefore quite possible that subsequent additions of the element may cause its concentration to exceed the narrow limits required for optimal effect. A specific action in Schmidt's method cannot be attributed to the chlorides of the alkaline-earth metals and magnesium, since they can be replaced by the alkali chloride; the chloride is the important component (Erie Tigdo and Arthur Schleede, Ber. 1923, 56, [B.] 674; Chem. Soc. Abstr. 1924, ii. 242). It has been proposed to use this property of zinc sulphide in the construction of an actinometer and for photometric purposes (Henry, Compt. rend. 1899, 128, 94). The phosphorescent sulphide glows when exposed to X- or to Becquerel rays; to the α -radiation from radium (Chem. News, 1903, 157; Becquerel, Compt. rend. 1904, 137, 629; Bamstead, Phil. Mag. 1908, [vi.] 15, 432), and under the influence of ozonised oxygen (Schenck and Mihr, Ber. 1904, 37, 3464). When zinc sulphide is heated with manganese nitrate and a number of other substances at 1200°, the product exhibits triboluminescence (Karl, Compt. rend. 1907, 144, 841).

According to J. Schmidt (Ber. 1922, 55, 3988) a highly phosphorescent zinc

be made by taking equal weights of pure zinc sulphate and sodium acetate, dissolving in water, and treating the hot solution with hydrogen sulphide until precipitation is complete. The zinc sulphide is washed by decantation, dried on the water-bath, and the product (200 grms.) uniformly moistened with a solution of magnesium chloride (20 grms.), calcium chloride (10 grms.), strontium chloride (10 grms.) and crystalline barium chloride (10 grms.), to which 0.04 gm. of ammonium tungstate dissolved in 10 c.c. of water has been added. The mixture with the zinc sulphide is evaporated to dryness on the water-bath with occasional stirring. The product is slowly heated to redness in a crucible for an hour and maintained at this temperature for 30–40 mins., after which it is allowed to cool in the furnace. The soluble salts are removed by water and the residual zinc sulphide is dried on the water-bath. It exhibits a strong green fluorescence. (J. Soc. Chem. Ind. 1923, 94 A).

The following account of the preparation of a highly phosphorescent zinc sulphide is taken from Sci. Amer. May, 1923, through Amer. Jour. Pharm. July, 1923, 568:—

A new process has been devised for making zinc sulphide, a compound which is used for many purposes for which phosphorescent salts are utilised. Equal weights of pure zinc sulphate and sodium acetate are dissolved in hot water; a stream of hydrogen sulphide is allowed to flow through the solution, which is kept hot, until precipitation is complete. After the zinc sulphide has settled, the liquid is syphoned off, the sulphide washed with hot water by decantation, filtered out, washed thoroughly again, and then dried on a water-bath. About 200 parts of the sulphide thus obtained is uniformly moistened with a solution containing 20 parts of magnesium chloride, 10 parts of calcium chloride, 10 parts of strontium chloride, and 10 parts of crystallised barium chloride, all being dissolved in 22 parts of water. Before this solution is added to the zinc sulphide, it is mixed with 10 parts of a solution of ammonium tungstate, which contains 0.004 gm. of the salt per c.c. The mixture of the prepared chloride solution and the zinc sulphide is evaporated to dryness on the water-bath with constant agitation, and the dried mass is then transferred to a crucible and heated in a gas-muffle furnace. The heat should be applied gradually, so that it requires about one hour for the crucible to become red-hot, at which temperature it should be maintained for 30–40 mins., and then allowed to cool to room temperature in the oven. The soluble salts are removed by decantation and washing with water. The washed sulphide is then dried on the water-bath (Pharm. Journ. Sept. 1923). A. A. Guntz (Compt. rend. 1923, 177, 479–482) has made a study of the phosphorescence of mixed crystals of zinc and cadmium sulphides. The phosphorescence of zinc sulphide changes in colour from green-blue to red with increasing quantities of cadmium sulphide. With 12 p.c., 20 p.c., and 30 p.c. of the latter substance, the phosphorescence is, respectively, lemon-yellow, orange, and red. The orange phosphorescence induced by the addition of traces of manganese to zinc sulphide is neither vigorous nor persistent, whereas cadmium sulphide produces no effect unless

present in fairly large quantities, and does not diminish the vigour or the duration of phosphorescence, the colour change being due to absorption of green light and not to phosphorogenic action (J. Soc. Chem. Ind. 1923, 42, 974 A).

A triboluminescent product may be prepared by heating to bright redness a dried mixture of 7 parts zinc carbonate and 3 parts of flowers of sulphur, previously made into a paste with water to which a small quantity of manganese sulphate is added. The resulting stonelike mass emits sparks of a yellowish light when scratched with a knife blade (Andrews, Trans. Amer. Electrochem. Soc. 1910, 18, 279; see also Tomaschek, Ann. Physik, 1921, [iv.] 65, 189, who has described the phosphorescence phenomena of zinc sulphide containing respectively, as phosphorogens, manganese, copper, bismuth, lead, silver, uranium, nickel, and cobalt).

Zinc sulphide may be obtained in a colloidal form by allowing it to remain in contact with water (Donnini, Gazz. chim. ital. 1894, 24, i. 219; Hausmann, Zeitsch. anorg. Chem. 1904, 40, 110); or by allowing a mixture of zinc sulphate, glycerol, and ammonium sulphide to stand for 3 days (Muller, Chem. Zeit. 1904, 28, 357), and in other ways.

Zinc sulphide, or a mixture of zinc sulphide and oxide, is used as a pigment. Griffiths' 'patent zinc white' is obtained by the addition of a soluble sulphide to zinc chloride or sulphate solution, drying the precipitate, and calcining it. It is raked out whilst hot into cold water, and levigated (J. Soc. Chem. Ind. 1885, 563).

A light-proof and weather-proof pigment may be obtained by precipitating zinc as a hydrated sulphide from an alkaline solution. The precipitate is then dehydrated at 300° until $\text{ZnS} : \text{H}_2\text{O} = 5 : 1$ (U.S. Pat. 884874, 1908; see also Griffiths' Eng. Pat. 750, 1883; Knight, Eng. Pat. 16220, 1884; J. B. Spence, Eng. Pats. 13462, 1885; 14128, 1885; 27420, 1907; Fr. Pat. 373027, 1906; Cowley, Chem. News, 1891, 63, 88; J. Soc. Chem. Ind. 1910, 99, 166).

A mixture of zinc sulphide and barium sulphate with some zinc oxide is known as *lithopone* or *zincolith*. It is obtained by precipitating hot concentrated zinc sulphate solution with barium sulphide. Rather less than 1 p.c. freshly-precipitated magnesium hydroxide and common salt are added and the precipitate is then washed, dried, crushed, mixed with 3 p.c. ammonium chloride, and heated. The mass, while still hot, is thrown into cold water, after which it is again dried and ground (Leyfert, Zeitsch. angew. Chem. 1902, 15, 802). It comes into commerce in different grades: yellow seal contains 11–18 p.c. ZnS, blue seal 22–30 p.c. ZnS, and green seal, 32–34 p.c. ZnS (Fr. Pats. 335115, 1903; 335358; U.S. Pat. 740072, 1903; Eng. Pats. 1836, 1837, 3768, 3769, 6521, 1903; D. R. PP. 199493, 202420, 163455, 167772, 202253, 202709; Riederer, J. Soc. Chem. Ind. 1909, 403).

Lithopone has the disadvantage of occasionally turning grey when exposed to light and moisture, due, it is supposed, to the reduction of the zinc sulphide to metal. On exposure to air in the dark the white colour is restored, presumably by oxidation. Various methods of protecting

the zinc sulphide have been employed and some have been patented. The presence of from 3 to 5 p.c. of zinc oxide acting as a film round the sulphide renders the colour more stable. On boiling the lithopone so protected with a concentrated solution of zinc chloride, the zinc sulphide again becomes sensitive to light (cf. O'Brien, *J. Phys. Chem.* 1915, 19, 113). A microscopical examination of lithopone shows that the particles of barium sulphate are coated with zinc sulphide (Gardner, *J. Ind. Eng. Chem.* 1916, 8, 794). Or the effect of light on zinc sulphide, see also P. Lenard, *Ann. Physik.* 1922, 68, 7 and 8, pp. 553-573; cf. Maus and Kempf, *Zeitsch. angew. Chem.* 1923, 36, 203.

Zinc carbonate ZnCO_3 occurs native as *smithsonite*, *calamine*, or *zinc spar*. It can be formed artificially by adding zinc sulphate solution to a solution of sodium hydrogen carbonate (Kraut, *Zeitsch. anorg. Chem.* 1896, 13, 1; *Eng. Pat.* 6752, 1902; *Fr. Pats.* 325587, 1902; 329079, 1903; 315888, 1901; *J. Soc. Chem. Ind.* 1902, 1457; *ibid.* 1903, 214, 752, 1007; Feist, *Arch. Pharm.* 1909, 247, 439). When the normal carbonate is employed, basic zinc carbonates are formed, the proportion of zinc oxide varying with the temperature and dilution of the solutions. The *zinci carbonas* of the British Pharmacopoeia has the approximate composition $\text{ZnCO}_3 \cdot (\text{ZnO})_2 \cdot 3\text{H}_2\text{O}$. At a red heat it loses carbon dioxide and forms zinc oxide.

According to Barbier basic zinc carbonate can be effectively employed as a pigment instead of white lead (*Fr. Pat.* 339151, 1903). It is prepared for this purpose by the electrolysis of a calcium carbonate solution with zinc as anode and carbon as cathode.

Zinc carbonate is a mild astringent to the skin, and is employed in dusting powders and lotion with, or instead of, zinc oxide.

According to Mikusch (*Zeitsch. anorg. Chem.* 1908, 56, 365) the only basic carbonate of zinc which exists in $5\text{ZnO} \cdot 2\text{CO}_2 \cdot 4\text{H}_2\text{O}$. All the others that have been described are solid solutions of zinc oxide and carbonate.

Zinc trithiocarbonate ammonia $\text{CS}_2\text{Zn}(\text{NH}_3)_2$ (Hofmann, *Zeitsch. anorg. Chem.* 1897, 14, 263); and **dihydroxylamine carbonate**

(Goldschmidt and Syngros, *ibid.* 1894, 5, 129) have been described.

Zinc cyanide $\text{Zn}(\text{CN})_2$ is prepared by precipitating zinc acetate with aqueous hydrocyanic acid or by heating zinc-dust with an organic substance containing nitrogen (Aufschläger, *Monatsh.* 1892, 13, 268). It is a white powder insoluble in alcohol and water, and has been used in the manufacture of alkali cyanides (D. R. P. 132294; *Chem. Zentr.* 1902, ii. 80). It forms double salts such as $\text{M}_2\text{Zn}(\text{CN})_4$ and $\text{M}_2\text{Zn}(\text{CN})_6$ (Berthelot, *Ann. Chim.* 1899, 17, [vii.] 458; Sharwood, *J. Amer. Chem. Soc.* 1903, 25, 570; see also Miller and Danziger, *ibid.* 1902, 24, 823; Fischer and Cuntze, *Chem. Zeit.* 1902, 26, 872). Herz (*J. Amer. Chem. Soc.* 1914, 35, 912) was unable to confirm the existence of $\text{NaZn}(\text{CN})_2 \cdot 2\text{H}_2\text{O}$. It also combines with ammonia (Varet, *Compt. rend.* 1887, 105, 1070; *ibid.* 1888, 106, 1080; *Ann. Chim.* 1897, [vii.] 10, 5).

Zinc nitrate is formed by dissolving zinc in

nitric acid. It is said to crystallise with 2, 3, 4, 6, and 9 molecules of water (Funk, *Zeitsch. anorg. Chem.* 1899, 20, 400; Vasilieff, *J. Russ. Phys. Chem. Soc.* 1909, 41, 744, 748). When heated for some time at 100° it forms basic salts (Athanasescu, *Bull. Soc. chim.* 1896, [iii.] 15, 1078; Terrell, *ibid.* 7, 553; Riban, *Compt. rend.* 1892, 114, 1357). It also forms double salts (Urbain and Lacombe, *ibid.* 1903, 137, 568). It can be obtained anhydrous as a pasty substance which crystallises on cooling by heating the hydrated salt in the vapour of nitric anhydride.

Zinc nitrite forms fine unstable needles (Matuschek, *J. Soc. Chem. Ind.* 1902, 705), and also gives double salts (Rosenheim and Oppenheim, *Zeitsch. anorg. Chem.* 1901, 28, 171; cf. Ray, *Chem. Soc. Trans.* 1917, 111, 159).

Zinc nitride Zn_3N_2 is formed by heating zincamide to dull redness, or zinc in a current of ammonia at 600° (White and Kirschbraun, *J. Amer. Chem. Soc.* 1906, 28, 2343). It is a green powder which becomes incandescent when moistened with water. A nitride may also be obtained by passing ammonia free from oxygen and moisture over zinc-dust (previously washed with a solution of ammonia and ammonium chloride, alcohol, and ether, and dried in a vacuum) for thirty minutes at 650° , the product being cooled to at least 200° before exposure to the air (Bentley and Stern, *Science*, 1921, 53, 143).

Zincamide or **zinc diamine** $\text{Zn}(\text{NH}_2)_2$ is a white amorphous powder readily decomposed by water, thus:

It is formed by the action of dry ammonia on zinc ethyl (Frankland, *Phil. Mag.* [iv.] 15, 149). A number of zincamine compounds have been prepared, the number of ammonia molecules depending upon the nature of the associated zinc salt and the temperature (cf. Ephraim and Bolle, *Ber.* 1915, 48, 638).

Zinc hydroxylamine $\text{Zn}(\text{O-NH}_2)_2 \cdot 3\text{NH}_3 \cdot \text{OH}$ is prepared by the action of anhydrous hydroxylamine on finely-divided pure zinc and treating the product with absolute alcohol. It forms glistening crystals which detonate and evolve ammonia when heated rapidly (Ebner and Schott, *J. pr. Chem.* 1908, [ii.] 78, 289).

Basic Zinc azoimide $\text{N}_2\text{ZnOH}(\text{?})$, see Curtius and Rissom, *J. pr. Chem.* 1898, [ii.] 58, 261.

Zinc azide is a white sandy powder, very hygroscopic and readily hydrolysed, and not more explosive than the alkaline earth azides. Obtained by shaking together finely divided zinc carbonate with an ethereal solution of azoimide until a portion of the solid is completely soluble in water (Wöhler and Martin, *Ber.* 1917, 50, 586).

Zinc borate or **hydroxyborate** $\text{Zn}_2(\text{B}_4\text{O}_7)_2(\text{OH})_2$ is prepared by precipitating an aqueous solution of zinc sulphate (500 grms. salt to 5-10 litres water) by the gradual addition, with constant stirring, of 443.6 grms. of borax solution, and 309 grms. 15 p.c. sodium hydroxide solution. The precipitate is then washed and dried (Holdermann, *Arch. Pharm.* 1904, 242, 567; see also Ouvrard, *Compt. rend.* 1900, 130, 335; Chastelier, *ibid.* 1891, 113, 1034; Borchers, *Zeitsch. anorg. Chem.* 1910, 68, 269). It is employed in the preparation of zinc powder for wounds.

Zinc perborate is obtained by the action of sodium peroxide or its hydrate and boric acid, or sodium perborate on a zinc salt or from basic acid and zinc peroxide hydrate. It is a white amorphous powder applicable to dermatology (D. R. PP. 165278, 165279).

Zinc boracite $6\text{ZnO} \cdot 8\text{B}_2\text{O}_3 \cdot \text{ZnI}_2$ is formed by passing a stream of carbon dioxide laden with iodine over a heated mixture of zinc and zinc borate (Allaire, Compt. rend. 1898, 127, 555).

Zinc phosphide Zn_3P_2 is obtained as a crystal line friable mass with metallic lustre, by heating zinc in phosphorus vapour in an atmosphere of dry hydrogen; or by passing a mixture of hydrogen phosphide and nitrogen over zinc heated to redness. It is insoluble in water and in alcohol, soluble in acids with evolution of hydrogen phosphide. Zinc phosphide possesses all the properties of free phosphorus, but is very stable and is used in medicine in place of the latter.

Johibois (Compt. rend. 1908, 147, 801) has also prepared the phosphide ZnP_2 (see also Rensault, *ibid.* 1873, 76, 283). For zinc phosphates and other compounds of zinc and phosphorus, see Bansa, *Zeitsch. anorg. Chem.* 1894, 6, 128, 143; Schwarz, *ibid.* 9, 249; Schulten, *Bull. Soc. chim. [iii.]* 2, 300; Ferrand, *ibid.* 1895, [iii.] 13, 115; Compt. rend. 1896, 12: 621, 886; Friedel, *ibid.* 1894, 119, 260.

Some natural zinc phosphates, viz. *hopewellite* $\text{Zn}_3\text{P}_2\text{O}_8 \cdot 4\text{H}_2\text{O}$; *parahopewellite*, same formula and *tarbuttite* $\text{Zn}_3\text{P}_2\text{O}_8 \cdot \text{Zn}(\text{OH})_2$, are described by Spencer (Min. Mag. 1908, 15, 1); *spencerite* $\text{Zn}_3(\text{PO}_4)_2 \cdot \text{Zn}(\text{OH})_2 \cdot 6\text{H}_2\text{O}$ is a basic zinc phosphate, like tarbuttite with water of crystallization, found in British Columbia; *hibbenite* $2\text{Zn}_3(\text{PO}_4)_2 \cdot \text{Zn}(\text{OH})_2 \cdot 6\text{H}_2\text{O}$ forms orthorhombic crystals of sp. gr. 3.213.

Zinc permanganate $\text{Zn}(\text{MnO}_4)_2 \cdot 6\text{H}_2\text{O}$ may be prepared by adding a concentrated solution of zinc sulphate to a similar solution of barium permanganate so long as barium sulphate is precipitated. The solution is filtered, and the filtrate evaporated to crystallization at a low temperature, or *in vacuo* over sulphuric acid, and the crystals finally dried at about 40° .

Zinc permanganate forms crystalline granules of a violet-brown colour, and is very soluble in water. In very dilute solutions it has been used successfully in the treatment of urethritis. It has no irritating action, but, like the potassium salt, it should never be compounded with alcohol, glycerol, sugar, or dry or fluid vegetable extracts as there may be danger of explosion owing to the readiness with which it is reduced and evolves oxygen (Merck, *J. Soc. Chem. Ind.* 1890, 409; Klobb, *Bull. Soc. chim. [iii.]* 9, 17).

Zinc orthosilicate Zn_2SiO_4 occurs native as *Willemite*. *Silicious calamine*, used to some extent as an ore of zinc, is a hydrated orthosilicate $\text{Zn}_2\text{SiO}_4 \cdot \text{H}_2\text{O}$. It is found in unmetamorphically-terminated rhombic prisms, and, like tourmaline, boracite, sugar, and other hemimorphic crystals, it is pyroelectric—that is, on warming, one end becomes positively, the other negatively, electrified.

Amorphous zinc silicate is prepared by precipitating a solution of zinc sulphate with sodium silicate. When heated with boric acid for 10 days at a high temperature it forms a white crystalline powder of ZnSiO_3 insoluble in acids

and isomorphous with the mineral *enstatite* (Traube, *Ber.* 1893, 26, 2735).

For some double zinc silicates, see Wyrnoff, *Bull. Soc. Franç. Min.* 1896, 19, 219; Wolff, *Zeitsch. Krist. Min.* 1900, 33, 147; Duboin, *Compt. rend.* 1905, 141, 254.

Zinc selenide ZnSe is formed by the direct union of its elements. It has a brilliant yellow colour, $D_{20}^{25} 5.29$, and does not fuse up to 1100° (Chikashige and Kurosawa, *Mom. Coll. Sci. Kyoto*, 1917, 2, 245; see also Fonze-Diacon, *Compt. rend.* 1900, 130, 832). Decomposes on drying (Moser and Atynski, *Monatsh.* 1925, 45, 235).

Zinc chromate v. Chromium.

Zinc also forms *arsenates*, *thioarsenates*, and *arsenites* (Reichard, *Ber.* 1894, 21, 1019; *ibid.* 1893, 31, 2163; Lefèvre, *Compt. rend.* 1890, 110, 405; Preis, *Annalen*, 1890, 257, 178; Avery, *J. Amer. Chem. Soc.* 1906, 28, 1155); *antimonates* and *thioantimonates* (Sanderens, *Bull. Soc. chim.* 1899, [iii.] 21, 47; Pouget, *Ann. Chim.* 1899, [vii.] 18, 508); *tellurates* (Guthrie, *Zeitsch. anorg. Chem.* 1902, 31, 340); *plumbates* (Hochmel, *Arch. Pharm.* 1896, 234, 397); *ferrocyanides* (Stone and Ingen, *J. Amer. Chem. Soc.* 1897, 19, 542; Miller and Matthews, *ibid.* 547), and other compounds.

ORGANIC COMPOUNDS OF ZINC

Zinc acetate $\text{Zn}(\text{C}_2\text{H}_3\text{O}_2)_2 \cdot 2\text{H}_2\text{O}$ is prepared by neutralising acetic acid with zinc carbonate or oxide. It forms thin, soft, white, glistening translucent plates, or monoclinic crystals of pearly lustre soluble in water and in alcohol (Ley, *Zeitsch. physikal. Chem.* 1899, 30, 243). It closely resembles the sulphate in its action and uses.

Zinc oleate (*shoemaker's zinc oleate*) is prepared by dissolving 32 grms. of hard soap shavings in 180 c.c. of distilled water, heating if necessary, 64 grms. of zinc sulphate are dissolved in 64 c.c. of boiling water and added to the former solution, after stirring, the oleate is separated, washed with hot water until free from sulphate, cooled, dried, and powdered (Naylor, *Pharm. J.* 1901, 66, 392). It is used in medicine as a mild astringent ointment and as an absorbent dusting powder to retard perspiration.

Zinc stearate is formed by the interaction of zinc acetate and sodium stearate. It is a fine white, tasteless powder, used for similar purposes as the oleate.

Zinc valerate $\text{Zn}(\text{C}_4\text{H}_7\text{O}_2)_2$ is prepared by mixing zinc sulphate with sodium valerate. It forms white, lustrous, pearly scales, or a white powder having the odour of valeric acid and a sweet, astringent metallic taste. It is employed in medicine.

Zinc oxalate, **propionate**, **tartrate**, **sallylate** and **lactate** have also been prepared. The last of these has been recommended for use mordanting cotton and other vegetable fibre (Eng. Pat. 372, 1896; *J. Soc. Chem. Ind.* 1890).

Zinc sulphanilate $(\text{NH}_4\text{C}_6\text{H}_4\text{SO}_3)_2 \cdot \text{Zn}_2\text{Cl}_2$ is sold under the trade name of 'nizin,' a non-irritant antiseptic.

For the preparation of *zinc tannate*, Villon, *Bull. Soc. chim.* 1890, [iii.] 3, 784.

Zinc antipyrine salicylate is formed when a dilute solution of sodium salicylate and antipyrine is mixed with a solution of zinc chloride or sulphate. It forms colourless needles, m.p. 75°–76° (decomp.), sparingly soluble in cold, and more so in warm, water, alcohol, and ether (Schuyten, Chem. Zentr. 1898, ii. 704).

Zinc boropierate (*Chrysyl*) is obtained by the saturation of boropieric acid (prepared by boiling together 349 grms. picric acid, 62 grms. boric acid, and about 4 grms. of water) with 8 grms. of zinc oxide. It is a yellow powder used as a medicinal antiseptic (Monteil, J. Soc. Chem. Ind. 1908, 354).

Zinc boro-diortho-hydroxybenzoate

m.p. 100° (decomp.), is obtained by mixing 1 part boric acid with 1 of zinc carbonate, or 3 of salicylic acid, and adding the mixture in small portions to 10 times the weight of water at 65°. The mixture is agitated until no more carbon dioxide is evolved, when it is filtered and allowed to crystallise (Fr. Pat. 4116, 1910; J. Soc. Chem. Ind. 1910, 976).

Zinc compounds of 2-hydroxynaphthalene sulphonic acid-1-azo-β-naphthols have been prepared by treating 1-amino-2-naphthol sulphonic acids in concentrated aqueous solution, or in suspension, with alkali nitrite and an equivalent amount of zinc sulphate. The product so obtained is then made to react with a concentrated alkali solution of β-naphthol. The products dye wool in acid solution, bluish-red to violet shades, which turn bluish-black on subsequent treatment with a dichromate (U.S. Pat. 807442, 1905).

Basic zinc formaldehyde hydrosulphite is formed by adding 1 molecule of zinc to a mixture of 2 molecules of sulphurous acid and 2 of formaldehyde and then reducing the mixture by another molecule of zinc (U.S. Pat. 814032, 8124, 1906; J. Soc. Chem. Ind. 1906, 311, 217).

By the interaction of zinc-dust, sulphur dioxide, and aqueous formaldehyde, a difficultly soluble *zinc formaldehyde sulphoxylate*, or a readily soluble *zinc formaldehyde hydrosulphite* is formed, according to the conditions of the experiment (Eng. Pat. 81, 1906; J. Soc. Chem. Ind. 1906, 260; see also *ibid.* 1908, 1058; Becker, *ibid.* 1910, 43, 856; Fromm and Palma, *ibid.* 1906, 39, 3317; D. R. PP. 214041, 172217).

Zinc indigo white $\text{C}_{14}\text{H}_{10}\text{O}_2\text{N}_2\text{Zn}$ (?) is produced by the action of zinc chloride on calcium indigo white; of zinc oxide on indigo white in boiling naphthalene, and of zinc dust on indigo white in boiling naphthalene. It crystallises in lustrous leaflets (Binz, J. pr. Chem. 1901, ii. 63, 497).

Zinc gelatose is obtained by dissolving gelatose (formed by the action of superheated steam on gelatin) in dilute alcohol, adding a solution of a zinc salt and precipitating with alcohol. It is an amorphous powder, soluble in water, but insoluble in ether, benzene, and chloroform. It is said to be a valuable astringent without any irritating action on the mucous membrane (U.S. Pat. 698604, 1902).

Zinc chlorophyll is obtained by the action of zinc hydroxide and carbon dioxide on an extract

resembles chlorophyll in properties. When treated with alkalis it yields a substance closely analogous with alkachlorophyll, but containing zinc instead of magnesium (Marchlewski, Biochem. Zeitsch. 1909, 16, 3).

Zinc p-haemoglobin $\text{C}_{75}\text{H}_{113}\text{Zn}_2\text{S}_2\text{FeO}_{12}$ formed by shaking blood with zinc-dust or by the action of zinc salts on crystalline blood pigment, is a non-toxic compound, which has been recommended for use in the treatment of chlorosis (Grahe, Chem. Zentr. 1894, i. 636).

Zinc chloride forms stable double salts with diazo or tetrazo compounds of amino-azo or diamino-azo bodies which can be employed in dyeing (Eng. Pat. 1645; J. Soc. Chem. Ind. 1897, 40).

The diazo solution is prepared in aluminium or enamelled iron vessels, the requisite amount of zinc chloride is then added gradually with continual stirring. The double salt is formed as a voluminous precipitate, which, after settling, is filtered. When mixed with cold tragacanth thickening these double salts may be preserved unchanged for several days.

The goods prepared with sodium β-naphthol, to which sodium acetate is added, are printed with this paste, and then passed through a weak hydrochloric acid bath, washed, and soaped. The most satisfactory results have been obtained with α-naphthylamine hydrochloride, which yields a bright cardinal of a yellowish tone (Smirnoff and Rosenthal, Färber-Zeit. 7, 442).

Zinc chloride also forms double compounds, with fatty acids, with aliphatic compounds having a basic character, with aromatic bases containing one benzene nucleus, and with such compounds as piperidine, pyridine, and picoline (Lachowicz and Bandrowski, Monatsh. 1888, 9, 510; Bose, Amer. Chem. J. 1898, 20, 246; Bömer, Zeitsch. Nahr. Genussm. 1898, [viii.] 541).

The *zinc alkyl compounds* are formed, for the most part, by the action of the required alkyl iodide on zinc (Frankland and Duppa, Annalen, 1864, 130, 118; Gladstone and Tribe, Chem. Soc. Trans. 1879, 569; Fileti and Cantalupo, Gazz. chim. ital. 22, ii. 387; Ipatieff, J. pr. Chem. 1896, [ii.] 53, 257; Simonowitsch, Chem. Zentr. 1899, i. 1066; Worobéeff, *ibid.* 1907; Böhm, *ibid.* 1907; Ragosin, J. Russ. Phys. Chem. Soc. 1892, 24, 549; Lachman, Amer. Chem. J. 1900, 24, 31; J. Amer. Chem. Soc. 1901, 23, 897; Granichstädten and Werner, Monatsh. 1901, 32, 315; Haase, Ber. 1893, 26, 1052; Meyer, Chem. News, 1925, 131, 1).

Iocitsch (J. Russ. Phys. Chem. Soc. 1902, 34), by treatment of zinc and iodine with ether in a reflux apparatus, obtains a transparent ethereal solution of zinc ethyl iodide, which is identical in properties with the Grignard reagent, does not inflame in the air, and can be safely poured from vessel to vessel. Similar solutions of zinc methyl, isopropyl, amyl and allyl iodides can be obtained.

Zinc methyl is a colourless liquid, b.p. 46°, m.p. –40°, sp.gr. 1.386 at 10.5°, inflammable in air and decomposed by water. For its preparation, see Renshaw and Greenlaw, J. Amer. Chem. Soc. 1920, 42, 1472.

Zinc ethyl is a colourless liquid, b.p. 118°, m.p. –28°, sp.gr. 1.182 at 18°; it has similar properties to the methyl compound.

ZINC.

The zinc alkyl compounds are employed in the synthesis of many organic compounds (Grigorovitch and Pawloff, *J. Russ. Phys. Chem. Soc.* 1891, 23, 159; Bewad, *ibid.* 1900, 32, 420; Tichwinsky, *ibid.* 1903, 35, 155; Gwosdoff, *ibid.* 1907, 39, 1232; Lechman, *Amer. Chem. J.* 1896, 18, 372; Bamberger and Tichwinsky, *Ber.* 1902, 35, 4179; Menschikoff, *J. pr. Chem.* [ii.] 36, 347; Bewad, *ibid.* 1907, [ii.] 76, 62; Saytzeff, *ibid.* 98; Blaise and Maire, *Ann. Chim.* 1908, [viii.] 15, 556; *Compt. rend.* 1907, 145, 73; *ibid.* 1909, 148, 489; Blaise, *ibid.* 1907, 145, 1285; Blaise and Herman, *ibid.* 1908, 146, 479; Delacre, *Bull. Soc. chim.* [iii.] 48, 754; Wagner, *ibid.* [ii.] 42, 330).

Zinc ethoxide $\text{Zn}(\text{OEt})_2$, is formed by the action of zinc methyl on ethyl alcohol in an atmosphere of carbon dioxide, or, better, nitrogen or hydrogen. It is a white powder which cannot be distilled, is insoluble in ordinary solvents and readily absorbs moisture from the air. Zinc isobutyl oxide is prepared similarly by employing the corresponding alcohol (Tolkatscheff, *J. Russ. Phys. Chem. Soc.* 1901, 33, 469).

Zinc thiocyanate combines with pyridine to form an insoluble compound $[\text{Zn}(\text{C}_5\text{H}_5\text{N})_2][(\text{CNS})_2]$. This compound is formed by stirring pyridine into a solution of a zinc salt mixed with a concentrated solution of ammonium thiocyanate. The formation takes place preferably in neutral solution or a slight excess of pyridine: with great excess of pyridine the precipitate redissolves. This reaction may be used for the detection of zinc, one part of zinc in 200,000 parts of water may thus be recognised (G. Spacu, *Bul. Soc. Stiinte Cluj*, 1922, 1, 348-351; from *Chem. Zentr.* 1923, ii. 508, 1052).

Other zinc organic compounds have been described by Moitessier (*Bull. Soc. chim.* 1899, ii. 21, 336); Werner (*Zeitsch. anorg. Chem.* 1899, 21, 201); Rosenheim and Meyer (*ibid.* 1906, 49, 13); Grossmann and Schuck (*ibid.* 50, 1, 21); Ebler and Schott (*J. pr. Chem.* 1909, [ii.] 79, 72); also in D. R. P. 86148.

For methods of detecting and estimating zinc *v. ANALYSIS*.

Zinc, analysis of. The following methods are in use in the laboratories of the more important producers and consumers of zinc in the United States. Spellers are classified as A, high grade; B, intermediate; C, brass special; and D, prime western, the last a low grade used chiefly for galvanising.

Sampling.—A number of slabs should be sawn in half, and the saw-dust used as the sample. Fine drillings may be used. In neither case should a lubricant be used, and the drillings must be freed from iron by magnets.

Lead.—For the estimation of lead electrolytically, the sample (8.643 grms.) is covered with water in a 400 c.c. beaker, and 30 c.c. of nitric acid are then added gradually. The factor 8.643 differs from the theoretical factor (8.66) slightly, because lead dioxide cannot be dried completely. When action is complete, the solution is boiled to expel nitrous fumes, transferred to a 200 c.c. electrolytic beaker, diluted to 125 c.c. and electrolysed with a 5 ampere. Deposition is complete in 15 minutes. To insure complete de-

position, the covers and beaker are rinsed down with sufficient water to raise the level of the liquid 0.5 inch, and electrolysis continued for 15 minutes. The newly-exposed surface should remain bright. The anode is washed three or four times with distilled water, once with alcohol, and dried at 210°C. for 30 minutes. The number of decigrams of lead dioxide corresponds directly to the percentage of lead. The electrodes are cylinders of 20 mesh (per lineal cm.) platinum gauze. The anodes are 30 mm. in diameter and 30 mm. high, the cathodes the same height, but only 12 mm. in diameter. Both have stems of stout wire 10 cm. long.

In the absence of electrolytic appliances, lead is estimated as follows: The drillings (25, 15, 10, or 5 grms., according to grade) are treated with 300, 180, 120, or 60 c.c. (according to weight of drillings) of 'lead acid'—that is to say, dilute sulphuric acid saturated with lead sulphate, prepared by mixing 300 c.c. of concentrated acid with 1800 c.c. of water, and adding to the hot solution 300 c.c. of water in which 1 gm. of lead acetate has been dissolved. The 'lead acid' thus prepared is allowed to settle several days and then filtered. After all but 1 gm. of zinc has dissolved the solution is filtered, the undissolved residue washed with 'lead acid,' then washed back into the beaker and dissolved in a small quantity of hot dilute (1:1) nitric acid. The resulting solution is evaporated with 40 c.c. 'lead acid' until fumes arise. When cool, 35 c.c. of water are added, boiled, the first filtrate containing most of the zinc and a trace of lead is added, and the mixture left overnight. The lead sulphate is filtered on a Gooch crucible, washed with 'lead acid,' then with dilute (1:1) alcohol, and finally with strong alcohol. The Gooch crucible is placed in a porcelain crucible and heated for five minutes.

Iron.—The zinc (25 grms.) is dissolved in 125 c.c. nitric acid. The solution is boiled, diluted to 300 c.c., ammonium chloride (10 grms.) is added, and ammonia in sufficient amount to redissolve the zinc hydroxide. The mixture is boiled and filtered through a 11 cm. paper, which is washed with dilute ammonia and hot water. The ferric hydroxide is dissolved in hot dilute (1:4) sulphuric acid, the solution passed through a Jones reductor, which is washed with 150 c.c. of dilute sulphuric acid and 100 c.c. of water, the reduced solution being finally titrated with $\frac{N}{100}$ permanganate. Using

such dilute permanganate as this, it is essential to run a control with the same amounts of acid and water.

Cadmium.—The drillings (25 grms.) are covered with 250 c.c. water and 55 c.c. hydrochloric acid and left overnight. More acid is added 2 c.c. at a time, with an interval between each addition, so as to dissolve all but about 2 grms. of zinc with a minimum use of acid, about 60 c.c. in all usually sufficing. A piece of the undissolved zinc is transferred to a filter, the liquid is filtered, and the undissolved matter is washed with water, rejecting filtrate and washings. The undissolved matter is dissolved in nitric acid, and the solution evaporated with 20 c.c. of dilute (1:1) sulphuric acid until fumes arise. The residue is taken up with 100 c.c. of water, the mixture boiled and allowed to stand

overnight. The lead sulphate is filtered off and discarded. The filtrate is diluted to 400 c.c., 10 grms. ammonium chloride are added, and the solution saturated with hydrogen sulphide (1 hour). It is sometimes necessary to add a drop or two of ammonia to start the precipitation of cadmium sulphide. The impure cadmium sulphide is filtered off on a Gooch crucible and dissolved in 60 c.c. (more if necessary) of dilute (1:5) sulphuric acid by boiling for 30 minutes. The solution is filtered from asbestos and lead sulphide, diluted to 300 c.c. and cadmium reprecipitated as sulphide in presence of 5 grms. ammonium chloride. When much cadmium is present, a third precipitation may be necessary. The precipitate is dissolved in hot dilute (1:3) hydrochloric acid in a platinum dish, the solution evaporated with sulphuric acid to fuming, diluted, any filter fibres destroyed by addition of nitric acid and heating, which is continued to dryness and finally to 500°-600° or to dull redness, the cadmium being weighed as sulphate. (From a Report of a sub-committee on Methods of Analysis of Non-ferrous Alloys of the American Chemical Society, Abstract in Analyst, 1915, 369.)

Another method for the determination of cadmium in spelter and zinc ores is as follows: Ten grms. of spelter are dissolved in dilute nitric acid, and ammonia is added to remove iron, etc. From the filtrate a sulphide concentrate containing the cadmium is obtained by adding sodium sulphide until the precipitate becomes white; this is collected and dissolved by heating with 15 c.c. of sulphuric acid (1:1) until fumes are evolved. After dilution and removal of the lead sulphate, the filtrate is treated with sulphuric acid until it contains 20 p.c., then saturated with hydrogen sulphide to remove the bulk of the copper. The filtrate is diluted to 250 c.c. and again saturated with hydrogen sulphide. The cadmium sulphide is collected, washed free from zinc salts, and dissolved in nitric acid; the solution is evaporated to complete dryness with 1 c.c. of sulphuric acid (1:1), and the residue is heated to redness and weighed; it consists of cadmium sulphate plus a small quantity of copper oxide. The amount of the latter is determined iodometrically and deducted. In the case of ores the sample is dissolved in hydrochloric acid and the acidity of the filtered solution is adjusted to 1 p.c. A concentrate containing all the cadmium is then obtained by passing hydrogen sulphide into the liquid until precipitation of white zinc sulphide commences. The assay is finished as before (C. E. Barrs, J. Soc. Chem. Ind. 1924, 43, 77 T.; B. 520; see also Luff, Zeitsch. anal. Chem. 1924, 65, 97).

Zinc, technical analysis of. Ericson (Eighth Inter. Cong. App. Chem. 1912, vol. i. 183; Analyst, 1912, 521) gives the following method of analysing commercial zinc: The spelter (20 grms.) is covered with 100 c.c. water and 50 c.c. dilute (1:3) sulphuric acid, and allowed to stand overnight. The lead, cadmium, and undissolved zinc are then filtered off, washed with hot water, returned to the beaker, and dissolved in 10 c.c. of nitric acid. The solution is boiled until brown fumes cease to be evolved, and is then diluted and filtered from any trace of tin or antimony oxide. If these are absent,

as is usually the case, the solution is diluted to at least 100 c.c. and 30 c.c. of ammonia and 5 to 10 grms. ammonium persulphate are added, and the solution boiled for 5 minutes. After 10 minutes, the lead peroxide is filtered off on a double filter (11 cm.) and washed four times with hot 10 p.c. ammonia and five times with hot water. The precipitate is washed back into the beaker and treated with a measured volume of hydrogen peroxide solution of known strength until dissolved. After addition of 15 c.c. of dilute nitric acid (sp.gr. 1.2) and 75 to 100 c.c. water, the excess of hydrogen peroxide is determined by titration with permanganate. If 1 c.c. of the permanganate corresponds to 1 mgrm. of iron, it should theoretically correspond to 1.85 mgrm. of lead; but experience shows that the factor 1.92 should be employed. Using this factor, the results check well with results obtained by the gravimetric chromate method, and the method is recommended for spelter containing 1 p.c. or less lead.

The ammoniacal filtrate from the lead peroxide is boiled until nearly neutral and a white precipitate appears. About 40 c.c. of dilute (1:3) sulphuric acid is then added, and boiling continued for 10 minutes. After diluting to 200 c.c. the solution is saturated with hydrogen sulphide, with occasional additions of water. The precipitate is collected on a double filter, washed and redissolved on the filter in a slight excess of hot dilute hydrochloric acid. Any copper present remains on the filter as sulphide and may be ignited and weighed as oxide. The solution of cadmium (and zinc) chloride is nearly neutralised with ammonia, and about 8 grms. of trichloroacetic acid (*cf.* Fox, J. Chem. Soc. 1907, 91, 964) dissolved in water is added—or more if necessary—to dissolve the cadmium sulphide which separates on neutralisation. The solution is diluted to 200 c.c. and the cadmium reprecipitated by hydrogen sulphide. The cadmium sulphide is filtered off, and converted into sulphate or phosphate.

Gravimetric method for the estimation of zinc.—An excess of ammonium thiocyanate, either solid or in concentrated solution, is added to a neutral solution of a zinc salt. Pyridine is then added with agitation (3 drops to each 0.19 of zinc sulphate) until present in excess. The precipitate, which has the composition

is collected and washed with an aqueous solution containing 0.3 p.c. of ammonium thiocyanate, 0.2 p.c. of ammonium sulphate, and 0.2 p.c. of pyridine. The precipitate is dried, heated over a Techs burner, and weighed as zinc oxide. The results are in good agreement with those obtained electrolytically (G. Spacu, Bul. Soc. Stiinta Cluj, 1923, 1, 361-364; from Chem. Zentr. 1923, ii. 508; J. Chem. Soc. 1923, 580).

Determination by means of cyanamide.—Ammonium acetate is added to a neutral solution of a zinc salt. Dilute ammonia is added till the precipitate redissolves, excess of cyanamide added, and the zinc cyanamide filtered, washed, heated to redness and weighed as zinc oxide (Markwald and Gebhardt, Zeitsch. anorg. Chem. 1925, 147, 42).

For the estimation of fluorine in zinc blende, see L. da Rocha-Schmidt and K. Kruger (Zeitsch.

anal. Chem. 1923, 63, 29; Analyst. 1923, 48, 628).

For the estimation of calcium in spelter and zinc ores, see C. E. Barrs (J. Soc. Chem. Ind. 1924, 43, 35).

The use of powdered magnesium is recommended for the precipitation of copper and lead in hydrochloric acid solution; to ensure complete separation of zinc which may be present, the precipitated metals should be boiled with hydrochloric acid and reprecipitated with magnesium. The zinc in the filtrate from the copper lead precipitate may be titrated directly with potassium ferrocyanide solution, since even large quantities of magnesium chloride do not interfere with the titration. If aluminium is used for the precipitation of the copper and lead it is necessary to remove the aluminium salts before the zinc is titrated. If the zinc solution contains not less than 7 c.c. of concentrated hydrochloric acid per 250 c.c. the presence of lead does not affect the titration of the zinc with ferrocyanide solution (E. G. R. Ardagh and G. R. Bongard, Ind. Eng. Chem. 1924, 16, 300, Analyst. 1924, 49, 249).

Zinc may be separated from iron by means of ammonia and ammonium chloride in one precipitation when the following procedure is adopted. The solution, which may contain as much as 0.2 gm. of zinc and 0.4 gm. of iron, is treated with a few drops of hydrochloric acid and evaporated to a volume of about 5 c.c., while this liquid residue is still warm 5 grms. of ammonium chloride are stirred into it and 10 c.c. of concentrated ammonia are added. The mixture is then diluted with 25 c.c. of water, the precipitate collected on a filter and washed with about 100 c.c. of ammoniacal ammonium chloride solution (5 grms. of ammonium chloride and 5 c.c. of concentrated ammonia per 100 c.c.). The filtrate is acidified with hydrochloric acid, diluted to 250 c.c., and the zinc titrated with standardised potassium ferrocyanide solution (22 grms. of ferrocyanide and 10 grms. of sodium thiosulphate per litre), uranium nitrate solution is used as indicator. The same method may be employed for the separation of zinc from aluminium, but the aluminium hydroxide requires rather more washing than does the ferric hydroxide (E. G. R. Ardagh and G. R. Bongard, Ind. Eng. Chem. 1924, 16, 297, Analyst. 1924, 49, 249).

The presence of aluminium in the solution does not affect the blank determination in the usual potassium ferrocyanide titration of zinc, but the results obtained for zinc in the presence of aluminium are high under the usual conditions of the titration. Magnesium chloride does not interfere with the titration of zinc by potassium ferrocyanide, even when present in large quantities, and powdered magnesium may be used with advantage to precipitate copper and lead in hydrochloric acid solution. In order to separate the zinc completely from the precipitated metals, the latter must be filtered off, boiled with concentrated hydrochloric acid, and reprecipitated with magnesium. The magnesium used should be as free as possible from iron, and care must be taken that no copper goes back into solution. Correct results for zinc by titration with potassium ferrocyanide can be secured in the presence of lead, provided

that 7-10 c.c. of concentrated hydrochloric acid are present in 250 c.c. of the solution (E. G. R. Ardagh and G. R. Bongard, Ind. Eng. Chem. 1924, 16, 300; J. Soc. Chem. Ind. 1924, 43, B. 386).

Importance of zinc in the nutrition of animals.—According to Bertrand and Benson (Bull. Soc. chim. Biol. 1924, 6, 203), it is impossible to remove all traces of zinc from natural food materials without also removing vitamin B, with which the zinc appeared to be associated. A synthetic food, based on the composition of wheat, containing potato starch, casein, cellulose, lactose, calcium lactate, calcium chloride, and other salts was used. Mice receiving the synthetic food with the addition of an amount of zinc as sulphate equivalent to that present in a normal diet of wheat lived for periods 25-50 p.c. longer than those receiving the synthetic food alone. Analysis of the bodies after death showed that, in the absence of any supply of zinc in the food, the amount present at the beginning is retained throughout life, whilst, if zinc be given, the original amount present is about doubled (J. Soc. Chem. Ind. 1924, 43, B. 572).

The world's production of zinc.—In 1913 the total output of zinc in the world was 981,000 tons, a figure which fell to 445,000 tons in 1921, rising to 722,000 tons in 1922, and over 864,000 tons in 1923. Of the 1923 production the United States produced the largest quantity, namely, 481,000 tons, Belgium following with 138,000 tons (J. Soc. Chem. Ind. 1924, 43, 725).

ZINC BLENDE, BLENDE, or SPHALERITE. Zinc sulphide ZnS , crystallised in the cubic system with tetrahedral hemihedrism. The name blende is an old mining term, from the German blenden, to blind or deceive, because the mineral was frequently confused with galena, hence also the terms *galena inanis*, *pseudo galena*, and *mock lead*. With a qualifying prefix it has been applied to a variety of minerals¹ which possess in common a more or less metallic lustre often combined with a certain degree of translucency. It is therefore necessary to distinguish the present mineral as zinc blende. The name *sphalerite*, introduced by E. F. Glocker in 1847, has the same meaning, from *σφαλερός*, *deceptive*.

Crystals are of frequent occurrence, but, as a rule, the faces are much rounded and the form is further obscured by twinning. An important crystallographic character is the presence of perfect cleavages in six directions parallel to the faces of the rhombic dodecahedron, adjacent cleavages being inclined to one another at angles of 120° or 90° . Massive material with coarse or fine granular texture and usually a crystalline fracture, due to the cleavage, is more common. Compact material with a shelly concentric structure and reniform surface ('liver blende') also occurs. When pure and free from iron the mineral is white or pale yellowish; more often, however, the colour is dark brown to black ('black jack') with a

¹ E.g. cadmium-blende (=greenockite), silver-blende (=pyrrargyrite and proustite), mercuric-blende (=cinnabar), copper-blende (=tennantite), manganese-blende (=alabandite), samarskite-blende (=gasthite), pitchblende, hornblende, &c. Analogous terms occurring in many old compound names of minerals are glance, pyrites (Ger. Eisen), and spar.

resinous, adamantine, or sub-metallic lustre. This darker coloured material when scratched with a knife (H. 3½-4) always yields a brown streak or powder, which readily distinguishes the mineral from galena; it is also much lighter (sp.gr. 3.0-4.1). The lighter coloured material is sometimes perfectly clear and transparent; e.g. the small, beautifully developed tetrahedral crystals found singly in cavities of the white crystalline dolomite at Binn in Valais, Switzerland; and the large, pale yellow cleavage masses from Pico de Europa in Santander, Spain. The latter contains only 0.16 p.c. Fe, and has sp.gr. 4.098, and refractive index n_D 2.369. Transparent crystals of a rich ruby-red colour ('ruby-blende') are found in Flintshire and elsewhere. Certain specimens of the massive mineral display a bright phosphorescence when scratched with a knife or struck with a pick.

The pure mineral contains 67 p.c. Zn, but usually this is partly replaced isomorphously by 1-2 p.c. of iron, which may range up to 26 p.c. A black ferrous zinc-blende from Marinato in Colombia, South America, containing 11-15 p.c. Fe, has been called *marmatite*. Cadmium is usually present in small amount (traces to about 0.5 p.c., but ranging up to 3.2 p.c.). Gallium and indium were discovered in zinc-blende; and these elements, as well as germanium and thallium, can be detected spectrographically in most samples of the mineral. Other metals occasionally found in small amounts are silver, mercury, copper, lead, manganese, and tin; but these are perhaps present as impurities. The stanniferous zinc-blende of Freiberg, Saxony, for example, encloses minute needles of cassiterite. The mineral dissolves in hydrochloric acid with evolution of hydrogen sulphide. At a temperature of 1020° it is transformed into the hexagonal modification wurtzite (*q.v.*). In zinc-blendes containing more iron the inversion temperature and the density are lower, whilst the refractive index is higher; e.g. for material from Breitenbrunn, Saxony, containing 17 p.c. Fe (sp.gr. 3.935, n_D 2.47), the inversion temperature is 880°. On the stability relations and artificial production of the two modifications of zinc sulphide, v. E. T. Allen and others (*Amer. J. Sci.* 1912, 34, 341; 1914, 38, 393).

Zinc-blende is the commonest ore of zinc, and by its alteration it gives rise to the secondary ores smithsonite and hemimorphite. It occurs in metalliferous veins, as bedded deposits, and as pockets in limestones; and is sporadically distributed through sedimentary rocks, sometimes replacing fossil shells. It has been observed on old mine timbers, having, no doubt, been formed by the reducing action of the organic matter on solutions of zinc sulphate produced by the oxidation of pre-existing zinc sulphide. In most instances zinc-blende occurs with galena, there often being a very intimate association of the two minerals. 'Huasciolite,' at one time believed to be a homogeneous mineral, is such a mixture. The mixed ores (e.g. those of Broken Hill in New South Wales) can be separated by an electro-magnetic process, since the small amount of iron present in the zinc-blende causes it to be slightly magnetic. In addition to its principal use as an ore of zinc, the mineral is also a source of sulphuric acid,

since sulphur dioxide is given off when the ore is roasted. The mineral is also used directly for the manufacture of zinc white (ZnO) and zinc-vitriol; in the former case the vapour of reduced zinc is oxidised in a current of warm air; and in the latter the ore, either before or after roasting, is treated with sulphuric acid. L. J. S.

Refraction and absorption of light by zinc-blende at temperatures up to 700°.—Measurements made of the refractive index and absorption of zinc-blende coloured slightly greenish-yellow for temperatures ranging from 80°-700°, and for wave-lengths between about 400 μ and 800 μ , indicated that in the visible spectrum the dispersion is normal and attributable principally to an oscillator with a frequency in the ultra-violet. The refractive index increases with temperature, and considerably more rapidly for light of short wave-length than for light of long wave-length. Thus for $\lambda = 436\mu$, the results show that the refractive index, n_λ at t° , is given by

$$n_\lambda = 2.4885(1 + 3.8695 \times 10^{-5}t + 17.9 \times 10^{-9}t^2)$$

Similarly, for $\lambda = 546\mu$,

$$n_\lambda = 2.3870(1 + 2.7508 \times 10^{-5}t + 11.1 \times 10^{-9}t^2)$$

and for $\lambda = 578\mu$,

$$n_\lambda = 2.3717(1 + 2.5826 \times 10^{-5}t + 9.5 \times 10^{-9}t^2)$$

The transparency of zinc-blende increases with increasing wave-length of the light transmitted and decreases rapidly as the temperature increases. A minimum transparency observed in the mean or extreme red region of the spectrum is attributable to an impurity present in the blende. With increasing temperature, the region of selective absorption is displaced from the ultra-violet towards the visible region of the spectrum (Maria Mell, *Zeitsch. physikal. Chem.* 1923, 16, 244-265; *J. Chem. Soc.* 1923, ii, 513).

The ignition temperature of zinc blende is lowered only to a small extent by increasing the oxygen content of the air; in pure oxygen this temperature is 25° below that in ordinary air. Other conditions being equal, the rate of oxidation of blende varies very nearly directly as the partial pressure of oxygen in the surrounding air, consequently the sulphur dioxide content of the roaster gas varies directly, and the time required for roasting inversely, as the oxygen content of the air supply. The amount of zinc sulphate formed at any temperature is greater with enriched air than with ordinary air. The addition of oxygen to the air supply of a furnace roasting zinc blende will increase its capacity, reduce the fuel consumption, and increase the proportion of sulphur dioxide in the gases, hence the capacity of the sulphuric acid plant will be increased and the cost of running is reduced (B. M. O'Harra, W. Kahlbaum, E. S. Wheeler, W. J. Darby, *Trans. Amer. Inst. Min. Met. Eng.* Mar. 1924; *J. Soc. Chem. Ind.* 1924, 43, B. 385).

ZINC-DUST is usually obtained as a by-product from zinc smelters, but it is also made by blowing gas against a stream of liquid zinc or by grinding. Such dusts contain varying amounts of impurities, some of which are undesirable for certain uses. Microscopic examination has shown that the grains of zinc-dust consist of metallic globules coated with crystals

of zinc oxide which prevent the globules from uniting.

The chief properties for which zinc-dust is used may be summarised as follows: (a) Reducing properties, as in the dye industry, for reducing nitro compounds to organic amines and in preparing sodium hydrosulphite for the reduction of vat colours; (b) the property of precipitating metals from their solutions, in purifying zinc-sulphate solutions for electrolysis or for the manufacture of lithopone; (c) the property of combining with dry oxygen only at a high temperature, and of giving with moist air a basic carbonate or with sea air an oxy-chloride which protects the metal from further alteration. These properties have led to application in painting iron objects, sherardising (i.e. immersing iron objects in zinc-dust at 300°C.), galvanising cast-iron and metallisation (i.e. deposition by projection of a layer of zinc on the surface of a metal) (Met. & Chem. Eng. 1923; J. Soc. Chem. Ind. 1923, 455).

Zinc-Dust (valuation of). Klemp has devised a process for the above purpose which depends on the power of zinc to reduce potassium iodate to potassium iodide in an alkaline solution. When the solution is afterwards acidified, iodine is liberated by the interaction of the iodic and hydriodic acids, and is distilled off from the mixture into potassium iodide solution, and titrated with thiosulphate. The details of the method are as follows:—

0.5–1 gm. of the well-mixed zinc-dust is weighed in a tube, and poured into a 200 c.c. stoppered flask, the tube being again weighed. For every 0.1 gm. of zinc present, 10 c.c. of a solution of alkali (containing 370 grms. of potassium hydroxide, or 300 grms. of sodium hydroxide per litre), and 3 c.c. of a solution of potassium iodate (containing 15.25 grms. of potassium iodate per 300 c.c.) are measured into a beaker, and then poured into the flask. Some glass beads are added, and the flask stoppered and shaken for 5 mins. in the cold, no advantage being gained by heating it. Its contents are then washed into a 250 or 500 c.c. flask, and made up to the mark with water. 100 c.c. are now pipetted into the retort of a Töpfer's apparatus (Zeitsch. anal. Chem. 26, 293), dilute sulphuric acid is added, and the apparatus filled with carbon dioxide. A solution of potassium iodide is placed in the receiver, and the retort heated, at first gently, and then more strongly till the contents are perfectly colourless. The stream of carbon dioxide is continued throughout the distillation, which generally occupies about 20 mins. The solution of iodine in potassium iodide is then transferred from the receiver into a flask, a standard solution of sodium thiosulphate added in slight excess, and the excess titrated back with weak standard iodine solution, starch being used as an indicator. After correcting for the excess, the quantity of zinc is calculated from the amount of thiosulphate used.

Klemp finds that the addition of powdered lead and iron to the zinc makes very little difference in the quantity of zinc found by this process, the results being a little lower in the presence of these metals.

The results by this method agree well with those obtained by Fresenius's method, but are

generally higher than those obtained by Drewson's and lower than those obtained by Töpfer's method (G. Klemp, Zeitsch. anal. Chem. 29, 253–266; J. Soc. Chem. Ind. 9, 968). For a volumetric method, depending on the amount of hydrogen evolved by the action of an acid on zinc-dust, v. *ibid.* 5, 145, 1886.

According to Edwards (Met. & Chem. Eng. 1919, 21, 1927) the hydrogen gas method is not on the whole suitable. The following process is recommended: 1 gm. of the zinc-dust is treated with 50 grms. of ferrous ammonium sulphate in 100 c.c. of water and constantly stirred. As soon as the zinc-dust is dissolved, 100 c.c. of sulphuric acid (1:10) is added and the solution is titrated with potassium permanganate.

ZINC FLOWERS. Zinc oxide produced by combustion; v. ZINC.

ZINC GREEN. Cobalt green, or Rinnmann's green; v. COBALT; also FIGMENTS. This term is also applied to a mixture of zinc yellow and Prussian blue.

ZINCITE. Native zinc oxide ZnO , crystallising in the hexagonal system. The crystals, which are of rare occurrence, possess the same degree of symmetry (hemimorphic-hemihedral) and very nearly the same angles as those of wurtzite (ZnS) (q.v.). The mineral is usually found as lamellar cleavage masses (there being a perfect basal cleavage), which are opaque to translucent and deep-red, rarely orange-yellow, in colour. The streak is orange yellow; sp.gr. 5.6. Manganous oxide (3–6 p.c.) replaces part of the zinc, and there is often a little ferric oxide present. Zincite is known only from the zinc mines at Franklin Furnace and Sterling Hill in Sussex Co., New Jersey, but it occurs there in some abundance, and is mined, together with franklinite and willemite, as an ore of zinc. Fragments of the mineral and of artificial crystallised zinc oxide have been used in the wave detectors of wireless telegraphy installations. White or yellowish crystals of hexagonal zinc oxide have often been observed in zinc furnaces, and sometimes in iron furnaces.

L. J. S.

ZINCKENITE. Lead sulphantimonite PbSb_2S_4 , crystallised in the orthorhombic system. The best crystals are of columnar habit, but their form is much obscured by twinning; these are known only from Wolfsberg in the Harz. Elsewhere the mineral is found as radiating aggregates of fine needles or compact fibrous masses; such material resembles stibnite in appearance, but differs from this in the absence of cleavage. The colour and streak are steel-grey, lustre metallic, opaque; sp.gr. 5.30–5.33; H. 3; soluble in hot hydrochloric acid with evolution of hydrogen sulphide. The mineral is not readily distinguished from the several other lead sulphantimonites of acicular habit (v. JAMESONITE and FEATHER-ORE). It occurs together with these and stibnite in metalliferous veins, and is no doubt often present in lead antimony ores, e.g. at Oruro, Bolivia. The name, which is sometimes spelt zinckenite, is after J. K. L. Zincken (1790–1862).

L. J. S.

ZINCOPYRIN. Trade name for phenyl-dimethyl-pyrazolone zinc chloride
($\text{C}_{11}\text{H}_{11}\text{N}_2\text{O}$) $_2\text{ZnCl}_2$

first obtained by Schuyten. Shining scales, m.p. 156°. Readily soluble in water, alcohol, and chloroform. Used in the treatment of inoperable carcinoma of the uterus.

ZINC-SPAR. Syn. with calamine; v. **ZINC**.

ZINC-SPINEL v. **GAHNITE**.

ZINC-VITRIOL. *Zinc sulphate* v. **ZINC**; also **GOSLARITE**.

ZINC WHITE v. **ZINC**.

ZINC YELLOW, or *Buttercup yellow* and *Zinc chromate*, v. **CHROMIUM**.

ZINGERONE v. **GINGER**; **KETONES**.

ZINGIBEROL $C_{15}H_{26}O$, a sesquiterpene alcohol occurring in the essential oil of ginger, possessing the fragrance of ginger. B.p. 154°–157°/14.5 mm. (Brooks, J. Amer. Chem. Soc. 1916, 38, 430), v. **GINGER**.

ZINKENITE v. **ZINOKENITE**.

ZINNWALDITE v. **MICA**.

ZINOL v. **SYNTHETIC DRUGS**.

ZIRCON. Native zirconium silicate $ZrSiO_4$, crystallising in the tetragonal system and homeomorphous with cassiterite and rutile. A little ferric oxide (0–3 p.c.) and sometimes thorium are present. The mineral varies considerably in its characters and appearance; and further, several altered and hydrated forms are distinguished by special names (*malacon*, *cyrtolite*, *oerstedite*, &c.). The transparent gem-varieties show a wide range in colour; brownish-yellow and red specimens are known as *hyacinth* (or jacinth), and yellowish and green as *jargon* (or jargoon). Fine sky-blue stones are said to come from Siam. The colour can usually be changed by heat, and some brownish-yellow stones are completely decolorised. With their brilliant adamantine lustre, these artificially decolorised stones ('Matura diamonds,' from Matura in Ceylon) may be mistaken for diamond. The hardness is 7½. The mineral is remarkable in showing a wide range in sp.gr. (4.0–4.7), and in optical characters, and these sometimes undergo a marked change when the crystals are heated to redness. These differences and changes suggest the existence of three modifications of zircon, which may occur as intergrowths in the zoned crystals (L. J. Spencer, Min. Mag. 1904, 14, 48). Possibly the so-called zircons of lower density are really hafnium silicates rather than zirconium silicate. In sixteen zircons from various localities, G. Hevesy and V. T. Jantzen (Chem. Soc. Trans. 1923, 123, 3218) estimated HfO_2 1.3 to 6 p.c., but unfortunately there is no statement of the densities of the materials examined.

Zircon occurs as a primary constituent of many igneous rocks, but, as a rule, only as minute crystals. Being heavy, hard, and resistant to weathering agencies, it collects in the beds of streams. Most of the gem material is obtained from gem-gravels in Ceylon and Australia. Rough and opaque zircon has been collected in considerable quantity from decomposed pegmatite in Henderson and Buncombe counties, North Carolina, and in Brazil. Zircon-bearing pegmatites occur also in Virginia (T. L. Watson, Trans. Amer. Inst. Mining Engin. 1917, 55, 936); and near Ashland in Virginia there is an important development of zirconiferous sandstone, containing 13–30 p.c. zircon as crystals and grains with an average diameter of 0.5 mm. Zircon is employed as a source of

zirconia (ZrO_2 , 67.2 p.c.), used in incandescent gas-lighting and in electric arc-lamps, and as a highly refractory material for lining furnaces and for chemical ware. A minor use is as an abrasive for grinding mother-of-pearl. Zircon, used in the natural crystalline form, does not melt at 2126°. At 1800°, some dissociation occurs, dense white fumes of silicon dioxide being formed at 1900°. The residue melts at about 2600°. Zirkite (that is, zircon containing excess of silica and some ferric oxide) does not melt at 1950° (C. Matignon, Compt. rend. 1923, 177, 1290; Chem. Soc. Abstr. 1924, 126, ii, 48).

References.—T. L. Watson and F. L. Heas, Zirconiferous Sandstone near Ashland, Virginia, with a summary of the occurrence, properties, and uses of zircon in general, Univ. of Virginia, Sci. Ser. 1912, 1, 267; W. T. Schaller, Zirconium Minerals, Min. Res. U.S. Geol. Survey, for 1916, 1917, ii, 377. L. J. S.

ZIRCONIUM. Sym. Zr. At.wt. 91.76 (Venable and Bell); 91.22 (Hönigschmid, Zintl, and Gonzales, Chem. Soc. Abstr. 1925, 128, ii, 174); 91.3 (Hevesy, Nature, 1925, 115, 335). Zirconia, an oxide of this metal, was identified in 1789 by Klaproth in the zircon of Ceylon, and this observation was confirmed by Guyton and Vauquelin.

It is the main constituent in zircon and malacon, which are found as accessory minerals in many metamorphic and igneous rocks (granites, syenites, elaeolite-syenites, basalts, amphibolites), and in baddeleyite (brazilite) in Ceylon, the Urals, Norway, and Australia. Large deposits of zirconia earth have been found in the Caldas region, about 130 miles north of São Paulo City, Brazil, and cover a mountainous plateau about 30 miles long and 15 miles wide (Meyer, Brazilian Review, 1916). The deposits are worked by the Foote Mineral Co., of Philadelphia (cf. Fletcher, Min. Mag. 1893, 10, 148; Hussak and Reiting, Zeitsch. Krist. 1903, 37, 567; Wodekind, Zeitsch. angew. Chem. 1908, 21, 2270; Ber. 1910, 43, 290). Brazilian zirconia deposits are feebly radioactive, and on heating evolve a gas containing argon and helium (Zeitsch. Elektrochem. 1908, 14, 585; Ann. Chim. 1898, [vii.] 13, 433; Chem. Soc. Trans. 1906, 89, 1568; 1908, 93, 350). The following minerals contain a high percentage of zirconium: *zirkelite* (zirconium titanate with thorium and rare earths), *eudialyte* (*eucolite*), *elpidite*, *catapleite* (zirconium double silicates of sodium and calcium), *polymignite* (Norway, a complex zircon-silicate, with titanium and tantalum oxides, columbium oxide, thorium, and the rare earths). Zirconium is a frequent constituent of rare-earth minerals (v. **CERITE EARTHS**), and is found also in *pitchblende*, *columbite*, and *tantalite*. *Baddeleyite* (q.v.) (82–94 p.c. ZrO_2) from Brazil, and *zircon* ($ZrSiO_4$) from monazite sands, &c. are the chief sources of zirconia. For methods of their analysis, see Powell and Schoeller, Analyst, 1919, 397; Chem. Soc. Trans. 1921, 120, 1927; Lundell and Knowles, J. Amer. Chem. Soc. 1920, 42, 1439; Analyst, 1920, 45, 342; Thompson, Trans. Ceram. Soc. 1919–20, 19, 153.

Separation and purification of zirconia.

1. *Fusion with sodium carbonate or hydroxide.*—The native silicate (zircon), disintegrated by heating and dropping into water, is treated

ZIRCONIUM.

with hydrochloric acid to remove metallic impurities (iron, &c.) and is fused with sodium carbonate or hydroxide (4 parts) containing 10 p.c. of sodium fluoride. When extracted with water the fused mass leaves an insoluble crystalline precipitate of sodium zirconate, which is dissolved in hydrochloric or sulphuric acid, and the zirconium hydroxide precipitated by ammonia (Monatsh. 1885, 6, 531; Chem. Soc. Trans. 1889, 58, 705; Amer. Chem. J. 1892, 5, 551; Marden and Rich, J. Ind. Eng. Chem. 1920, 12, 651; cf. Jackson and Shaw, J. Amer. Chem. Soc. 1922, 44, 2712; Wenger and Müller, Chem. Soc. Abstr. 1925, 128, ii, 1207).

2. *Decomposition with hydrofluoric or sulphuric acid, or their acid salts.*—Zircon is exposed to the vapour of hydrogen fluoride or heated with potassium hydrogen fluoride; in the latter case, the product, when boiled with hydrofluoric acid, leaves a deposit of potassium silicofluoride, whilst the more soluble potassium zirconofluoride crystallises out on concentrating the solution (J. 1859, 677; Ann. Chim. 1860, [iii.] 60, 257). Zircon can also be decomposed with hot concentrated sulphuric acid, or with fused potassium hydrogen sulphate (Ber. 1870, 3, 58; Annalen, 1876, 181, 232). When the ore is fused with KHSO_4 , the fused mass may be extracted with water and the metals precipitated as hydroxides and redissolved in concentrated hydrochloric acid. From the strongly acid solution zirconium is precipitated as phosphat $\text{Zr}(\text{HPO}_4)_2$. This is washed by decantation with hydrochloric acid and water and then dissolved in hydrofluoric acid. From this solution the zirconium is precipitated as hydroxide (de Boer, Zeitsch. anorg. Chem. 1925, 144, 190). Zirconium salts may also be purified by precipitation from boiling hydrochloric acid solution by sodium arsenate. The precipitate $\text{Zr}_3(\text{AsO}_4)_4$ affords a means for separating zirconium from hafnium, cerium, and thorium (Moser and Lessing, Monatsh. 1924, 45, 323).

3. *Reduction with carbon or calcium carbide.*—Crude zirconium carbide obtained by heating an intimate mixture of zircon and carbon in the electric furnace is heated in chlorine, and the resulting chloride dissolved in concentrated hydrochloric acid; the crystalline oxychloride, which separates from this solution, is decomposed by ammonia. Or a mixture of zircon, calcium oxide, and carbon is heated in the electric furnace (1030 amperes, 50 volts for 7 mins.; the product, when extracted with water and dilute hydrochloric acid, is decomposed by chlorine at 300° , yielding zirconium chloride (Compt. rend. 1893, 116, 1428; 1896, 122, 65; Zeitsch. anorg. Chem. 1902, 33, 81; Ber. 1903, 35, 3929; Chem. Zeit. 1907, 31, 654). Zircon may be mixed with 25 p.c. of carbon and treated with a stream of chlorine at 1000° – 1200° . From the mixture of chlorides thus formed zirconium oxychloride is obtained by crystallisation from aqueous solution. Heating this in air yields zirconium oxide.

4. *Other methods of purification.*—Zirconia is freed from silica by heating with potassium hydrogen fluoride when the latter oxide is eliminated as volatile silicon fluoride. Crude zirconia is rendered soluble by heating with strong sulphuric acid or by fusion with sodium hydroxide. Treatment of the product

with warm water leads to the separation of crystalline basic sulphate (Ber. 1904, 37, 2024; cf. Zeitsch. anorg. Chem. 1905, 45, 155; Rosster and Sanders, J. Soc. Chem. Ind. 1921, 40, 701). Zirconia is freed from iron by crystallising the oxychloride from strong hydrochloric acid (Chem. Soc. Trans. 1889, 58, 705; Amer. Chem. J. 1891, 5, 551; J. Amer. Chem. Soc. 1894, 16, 469). Ferruginous zirconium hydroxide, when dissolved in hydrochloric acid and boiled with sodium thiosulphate, gives the pure hydroxide mixed with sulphur. The addition of ammonia and ammonium sulphide to an iron and zirconium solution precipitates zirconium hydroxide, and ferrous sulphide, the latter being dissolved out with sulphurous acid. In the presence of tartaric acid the foregoing solution yields ferrous sulphide alone on adding ammonium sulphide; the concentrated filtrate, when mixed with excess of hydrogen peroxide, furnishes pure hydrated zirconium peroxide (Zeitsch. anorg. Chem. 1902, 33, 81). Brazilian zirconia earth (74.94 p.c. ZrO_2) is dissolved in mineral acid, and the iron and titanium removed from the dilute solution with ammonia and ammonium carbonate, the liquid being warmed until it gives no coloration with sulphuric acid and hydrogen peroxide. The acidified filtrate is boiled to expel carbon dioxide and the zirconium hydroxide precipitated with ammonia. The mineral may also be heated with magnesium in an atmosphere of hydrogen; the product extracted successively with ammonium chloride, hydrochloric acid, and potassium hydroxide to remove magnesium, iron, and silicon; the residue is heated in hydrogen, and then in chlorine or bromine, when zirconium chloride or bromide sublimes (Wedekind, Ber. 1910, 43, 290).

Zirconium is isolated only with difficulty owing to the readiness with which it combines with oxygen, nitrogen, carbon, silicon, &c. When reduced with carbon in the electric furnace zirconia yields zirconium containing either oxide or carbide, depending on the proportion of the reagents (Troost, Compt. rend. 1893, 116, 1227; Moissan, *ibid.* 1222; Greenwood, Chem. Soc. Trans. 1908, 93, 1843). The metal (97.7 p.c.) may be obtained by heating an intimate mixture of zirconium oxide and metallic calcium or aluminium in an exhausted iron tube, heated until reduction begins and the ignited mass extracted with water and dilute acids out of contact with air (Wedekind, Annalen, 1913, 395, 149; cf. Marden and Rich, J. Ind. Eng. Chem. 1920, 12, 651; Bureau of Mines, Bull. 186, 1921). A thick layer of pure zirconium is deposited upon a heated tungsten filament when the vapour of zirconium iodide unadmixed with other gases is passed over the filament (van Arkel and de Boer, Zeitsch. anorg. Chem. 1925, 148, 345). Boron or silicon reacts with zirconia in the electric furnace, but the product is contaminated with boride Zr_3B_4 or silicide. Amorphous zirconium (95–96 p.c. Zr) is obtained by heating potassium zirconofluoride with sodium under fused potassium chloride in closed iron vessels, the product being extracted with alcohol and then with hydrochloric acid. It is pyrophoric and behaves like a colloidal gel, retaining water with great tenacity. With acids it easily passes into a hydrosol (Wedekind and Lewis)

Lely and Hamburger (Zeitsch. anorg. Chem. 1914, 87, 209) obtained the element in a compact ductile form by heating the chloride with sodium in an exhausted steel bomb (see also Cooper, Trans. Amer. Electrochem. Soc. 1923, 209). By reducing the double fluoride with aluminium at the temperature of melting iron impure metallic zirconium (98 p.c.) is produced, but in the electric furnace an alloy of this element and aluminium is formed. Reduction of the double fluoride with magnesium in the electric furnace gives crystalline zirconium (94 p.c.), but sometimes contaminated with nitride. The product, containing 97-98 p.c. of zirconium, is pressed into rods, and then used as the terminals of an electric arc operating in hydrogen under diminished pressure; fusion takes place, and 99.8 p.c. zirconium is obtained. This resembles white cast iron, and has a hardness 7-8, sp.gr. 6.40 at 18°, sp.ht. 0.004, and heat of combustion (1 gm.) = 1958.7 cal., m.p. 1530° (Burgess), 1700° (Guertier and Puani). The amorphous variety, which is a black powder, and a bad conductor of electricity, is readily oxidisable, whereas the crystalline modification yields zirconia only at white heat. Zirconium is attacked by hydrogen fluoride, and at red heat by hydrogen chloride or chlorine, but is not appreciably affected by sulphuric, hydrochloric, or nitric acid; it is oxidised by fused potassium hydroxide or nitrate (Zeitsch. anorg. Chem. 1905, 45, 385; 1910, 65, 245; Zeitsch. Elektrochem. 1904, 10, 331; Annalen, 1910, 371, 367). An alloy of zirconium 65 p.c., iron 26 p.c., aluminium 7.7 p.c., and titanium 0.12 p.c., is highly resistant to acids, and not liable to oxidation. Ferro-zirconium has been used for the production of hard steel for armour plates and bullet-proof sheets. Zirconium carbide is hard enough to cut quartz, and might replace the diamond for glass-cutting.

The hot-rolling properties of steel containing 0.075 p.c.-0.32 p.c. S were observed in relation to the minimum zirconium content required to prevent red-shortness. Zirconium in steel reacted quantitatively with sulphur in the ratio corresponding with the formation of ZrS_2 , no excess being necessary as is required when manganese is used alone as a desulphurising agent. Zirconium also militates against the effect of iron sulphide and increases the capacity of manganese to combine with sulphur. Like manganese sulphide, zirconium sulphide is plastic at rolling temperatures and is visible on etching the metal as grey inclusions elongated by the mechanical treatment received. The normal sulphide, ZrS_2 , is soluble in hydrochloric acid (1:1), but if more zirconium than corresponds with this ratio is present in the steel, the sulphur is not evolved as hydrogen sulphide upon treatment with the acid, and it is suggested that the excess zirconium is partitioned between the metal and the normal disulphide, the latter forming possibly an insoluble zirconium-zirconium sulphide solid solution, the proportion of sulphur rendered insoluble being 10 p.c. of the zirconium in excess of that required to form the normal disulphide (A. L. Field, Trans. Inst. Min. Met. Eng. Feb. 1924; J. Soc. Chem. Ind. 1923, 1026 A.; 1924, 43, B. 470).

Zirconia (Zirconium dioxide) ZrO_2 occurs native as baddeleyite (q.v.) in monoclinic forms,

not isomorphous with cassiterite or rutile. When crystallised from borax a quadratic form of zirconia is produced isomorphous with rutile. Ignition of zirconium hydroxide, sulphate, oxalate, or nitrate yields the dioxide as a hard white powder. The density varies with the mode of preparation, unfused specimens having sp.gr. 5.4824 at 18.5°, whilst fused rods vary from 5.48 to 5.89. Zirconia melts at $2653^\circ \pm 10^\circ$ (3000°, Podszus) (Ruff and Lauschke, Zeitsch. anorg. Chem. 1916, 97, 73), and may be vaporised in the electric furnace (360 ampères, 70 volts). The vapour condenses to a fine powder which scratches glass. Its hardness is 6.5, between that of quartz and corundum. The sp.ht. of zirconia is 0.1076; it is a bad conductor of heat, and has a linear coefficient of expansion = 0.0000084, near to that of fused quartz (Nilson and Petterson, Compt. rend. 1880, 91, 232; Moissan, *ibid.* 1893, 116, 1222; Lehman, Dissert. Techn. Hochsch. München. 1910; Zeitsch. anorg. Chem. 1909, 65, 178). For its production from zirkite, see under ZIRKITE.

The solubility of zirconia in mineral acids depends on the temperature of ignition; after slight ignition it dissolves readily, but after strong ignition it becomes practically insoluble, although it is attacked by hydrofluoric and concentrated sulphuric acids. It resists fused cyanides and alkalis, but is easily attacked by fusion with potassium acid sulphate and fluorides.

When heated in the oxy-coal-gas flame zirconia becomes brilliantly incandescent, so that it may replace for certain special purposes the lime of the Drummond light, and it has been thus employed by Lannemann and others in spectroscopy and microphotography. It has received an important technical application in the Nernst lamp in which the incandescent body is composed chiefly of zirconia (85 p.c.), together with oxides (15 p.c.) of the yttrium series. This material conducts only at high temperatures, so that it requires to be first heated before the electric current can be transmitted.

Strongly ignited zirconia is very stable towards acids and alkalis, and as it is not fractured by sudden changes of temperature, it may be employed for crucibles in which platinum and quartz can be melted. Refractory vessels have also been made from zirconia mixed with 10 p.c. of magnesia or clay, phosphoric acid being employed as a binding material (Zeitsch. anorg. Chem. 1909, 65, 178).

Zirconia crucibles are moulded from the plastic mass made by kneading together gelatinous zirconium hydroxide and artificial or purified native zirconia, a little starch being added to keep the mass firm while drying. After 2 days the crucibles are gently heated at 50°-100°, and the temperature then raised gradually to 2000°-2300°. These crucibles are not affected by fused alkalis or alkaline bisulphates (Bayer, Zeitsch. angew. Chem. 1910, 23, 488; Ruff and Lauschke, *l.c.*; Podszus, Zeitsch. angew. Chem. 1917, 30, i. 17; Andley, Trans. Ceram. Soc. 1916-17, 16, 121; Rodd, J. Soc. Chem. Ind. 1918, 213 R).

Zirconia is a very good insulator, and mixed with good conducting material it is employed for electrical heating purposes, and may be used to prevent disintegration of the iridium in the

iridium furnace. It has found application as a substitute for bismuth prior to the use of Röntgen rays for medical purposes, and has been recommended as a non-irritant powder for covering the surface of wounds.

It is a good catalyst for the preparation of aliphatic esters by passing the mixed vapours of acids and alcohols over the oxide at 270°–290°.

The effect of additions of zirconia to a typical commercial ground coat enamel (borax 32, felspar 29, quartz 19, soda ash 9, sodium nitrate 5, fluorspar 4.7, cobalt oxide 0.8, manganese oxide 0.4 pts.) and to a base white enamel (borax 25.5, felspar 25, quartz 21, soda ash 3.5, sodium nitrate 3.0, cryolite 14.0, antimony oxide 3.0, zinc oxide 5.0 pts.) on the resistance of the enamel to impact, thermal shock, and acid attack, and on the opacity has been determined by Wolfram. All additions of zirconia made the enamel more viscous and thus increased the time of burning. The addition of zirconia to the smelter batches increased the resistance of the enamel to impact. Increased substitutions of zirconia for tin oxide in the mill increased the resistance to thermal shock, but increasing the amount of zirconia in the smelter batch decreased the resistance to thermal shock. The addition of zirconia to the smelter batch did not increase the resistance to attack by acid, but the substitution of zirconia for tin oxide in the mill gave a slightly increased resistance. Zirconia can be used as a satisfactory substitute for tin oxide in the mill additions as an opacifier (H. G. Wolfram, J. Amer. Ceram. Soc. 1924, 7, 1; J. Soc. Chem. Ind. 1924, 43, B. 218).

Zirconium hydroxide behaves as an amphoteric hydroxide, its compounds with the alkalis undergoing considerable hydrolysis in aqueous solution. The zirconates are produced either by adding zirconium salts (e.g. nitrate) to concentrated alkali solution, or by fusing zirconia with the alkaline hydroxides or oxides. The substances obtained by the wet process are probably adsorption products rather than definite chemical compounds, for prolonged washing gradually removes the alkali from the colloidal mass. The fusion process leads to *metazirconates* CaZrO_3 , Na_2ZrO_3 , and Li_2ZrO_3 , but even these products vary somewhat in composition. Other types, such as $\text{Li}_2\text{Zr}_2\text{O}_5$, have been described. When zircon (zirconium silicate) is fused with alkalis the crystalline silicozirconates are obtained, e.g. $\text{K}_2\text{O}(\text{SiO}_2, \text{ZrO}_2)$ and $\text{CaO}(\text{SiO}_2, \text{ZrO}_2)$, the latter being isomorphous with titanite (Ouvrard, Compt. rend. 1891, 112, 1444; 113, 80).

A zirconium hydroxide of the composition $\text{Zr}_2\text{O}_3(\text{OH})_4$, corresponding to the 5:4 basic zirconium chloride (v. *infra*), is obtained by adding ammonia to an aqueous solution of that compound; it appears to be chemically distinct from the normal hydroxide (Rodd, *loc.*).

Colloidal insoluble zirconium hydroxide (hydrogel) is produced by boiling solutions of zirconium oxychloride (Ruer, Zeitsch. anorg. Chem. 1905, 43, 282; van Benumelen, *ibid.* 1906, 49, 125). The hydrogel modification is prepared by adding ammonia to aqueous zirconium nitrate or by dissolving freshly-precipitated zirconium hydroxide in this solution (Müller, *ibid.* 1907, 52, 316).

There is no certain evidence of the existence

of a zirconium monoxide. The black powder assumed to be the monoxide is a mixture of metallic zirconium and the dioxide.

Zirconium peroxide is produced as a gelatinous precipitate by adding ammonia to aqueous zirconium sulphate containing hydrogen peroxide; or by the electrolysis of an alkaline sodium chloride solution in which zirconium hydroxide is suspended. The product is probably $\text{Zr}(\text{OH})_2 \cdot \text{O}_2 \cdot \text{H}_2\text{O}$, a hydrated form of ZrO_2 (Pissarjewski, Zeitsch. anorg. Chem. 1899, 25, 378; 1900, 31, 359; v. Bailey, Chem. Soc. Trans. 1886, 49, 481; 1889, 58, 705).

The alkali *perzirconates* $\text{Na}_4\text{Zr}_2\text{O}_{11} \cdot 9\text{H}_2\text{O}$ and $\text{K}_4\text{Zr}_2\text{O}_{11} \cdot 9\text{H}_2\text{O}$ are precipitated by alcohol, from cold aqueous alkaline solutions of the hydrated peroxide and hydrogen peroxide.

Zirconium hydride ZrH_2 , black powder, produced from metallic zirconium and hydrogen at red heat, burns in oxygen under ordinary pressure to the sesquioxide Zr_2O_3 , and in the compressed gas to zirconia. According to Schwarz and Konrad (Ber. 1921, 54, [B.] 2122), 10 gaseous hydride exists.

Zirconium fluoride ZrF_4 , anhydrous, sp.gr. 4.4333 at 16°, sparingly soluble in cold water, hydrolysed on warming, prepared by heating zirconia with ammonium hydrogen fluoride. The hydrate $\text{ZrF}_4 \cdot 3\text{H}_2\text{O}$, triclinic crystals, obtained by dissolving zirconia in hydrofluoric acid, is probably a hydrate of acid zirconyl fluoride $\text{ZrOF}_2 \cdot 2\text{HF} \cdot 2\text{H}_2\text{O}$.

Zirconofluorides. These double fluorides are of interest on account of their employment in the preparation of zirconium compounds and in the isolation of the element, and also because they illustrate the family relationship between zirconium and the other elements (silicon, titanium, and tin) of the fourth periodic group. Moreover, the existence of these well-defined crystallisable double salts distinguishes zirconium from the rare earth metals. They are produced by dissolving zirconium fluoride or oxide together with a metallic oxide or carbonate in aqueous hydrogen fluoride. The zirconofluorides corresponding with the general formula R_2ZrF_6 are the most stable, although other forms exist (Maignac, Compt. rend. 1860, 50, 952; Wells and Foote, Zeitsch. anorg. Chem. 1896, 10, 434; Amer. J. Sci. 1897, (iv.) 3, 466).

Potassium zirconofluoride K_2ZrF_6 , rhombic prisms, is the most important compound of this series; 100 parts of water dissolve 0.78 part of the salt at 2°, and 25.0 parts at 100°.

Zirconium tetrachloride ZrCl_4 can only be obtained pure by dry processes owing to its great tendency to undergo partial hydrolysis. It may be formed:

(i.) By the action of chlorine and sulphur chloride on heated zircon (Maignon and Bourron, Compt. rend. 1904, 138, 631). The chlorides of silicon and titanium are also produced in this process, but are readily separated owing to their greater volatility.

(ii.) The interaction at 300° of zirconium carbide, and chlorine (Wedekind, Zeitsch. anorg. Chem. 1902, 33, 81).

(iii.) Sublimation in chlorine of the product obtained by heating zirconia and phosphorus pentachloride in sealed tubes at 190° (Smith and Harris, J. Amer. Chem. Soc. 1896, 17, 448; v. Venable, *ibid.* 1894, 16, 469; Annalen, 1887,

239, 253; Compt. rend. 1885, 61, 109; 1872, 75, 1819; 1887, 104, 113; Ber. 1887, 20, 688).

The anhydrous chloride is a white crystalline sublimate of sp.gr. 2.803 fuming in moist air, reacting energetically with water, and combining with 1-8 molecules of dry ammonia (J. Amer. Chem. Soc. 1898, 20, 815, 839, 843; Ber. 1905, 38, 2611). It forms additive compounds with phosphorus pentachloride and sulphur tetrachloride, and double chlorides $B_2H_4 \cdot ZrCl_4$ with alcoholic pyridine

and quinoline hydrochlorides (Ber. 1905, 38, 812). For its reaction with methane and acetylene, see Venable and Deitz (Chem. Soc. Abst. 1923, ii. 170).

When zirconium tetrachloride is heated at about 250°C. with aluminium powder and a small quantity of aluminium chloride, in absence of air, it is reduced to zirconium trichloride, a brown, microcrystalline substance, which could not be obtained free from aluminium chloride. Zirconium trichloride is rapidly oxidised by air and decomposes water with evolution of hydrogen and formation of $ZrOCl_2$. When the trichloride is heated at about 330°C. it decomposes into tetrachloride and the dichloride $ZrCl_2$. The latter is a black, amorphous substance, which is almost insoluble in air free water, but is slowly oxidised in damp air. When heated above 600 C. the dichloride decomposes into the tetrachloride and zirconium (O. Ruff and R. Wallstein, Zeitsch. anorg. Chem. 1923, 128, 96-116; J. Soc. Chem. Ind. 1923, 42, 1220 A.)

Zirconium trichloride, obtained as a brown, microcrystalline solid, d^{20}_4 3.0, and the black dichloride formed by its dissociation at 330° generally resemble the titanium compounds (O. Ruff and R. Wallstein, Zeitsch. anorg. Chem. 1923, 128, 96).

Zirconium oxychloride $ZrOCl_2 \cdot 8H_2O$, colourless tetragonal prisms, the most characteristic product of hydrolysis of the tetrachloride, is somewhat sparingly soluble in concentrated hydrochloric acid, and is on this account utilised in the separation of zirconium. The addition of ether to an alcoholic solution of this oxy-salt produces a precipitation of metazirconium chloride $Zr_2O_3Cl_2$, corresponding with metastannic chloride. It is practically insoluble in strong hydrochloric or nitric acid, dissolves in water to an opalescent colloidal solution, and this liquid on dialysis furnishes metazirconic acid (J. pr. Chem. 1875, [ii.] 2, 219; Ber. 1907, 40, 803; Zeitsch. anorg. Chem. 1904, 42, 87; 1905, 43, 803; 48, 456; Compt. rend. 1912, 154, 1234). For zirconium chlorate, perchlorate, and iodates, see Venable and Smithey (J. Amer. Chem. Soc. 1919, 47, 1722).

A 5 : 4 basic zirconium chloride

has been described by Rödd (Chem. Soc. Trans. 1917, 111, 398), it gives a white curdy precipitate with any soluble sulphate. Zirconium oxychloride is very readily hydrolysed, forming complexes of the type $zZr(OH)_yZrOCl_z$, which react with the hydrochloric acid to form complex acids of the types $Zr(OH)_xCl_yH_z$, and $Zr(OH)_xCl_yH_z$ (Adolf and Pauli, Kolloid. Zeitsch. 1921, 20, 173).

Zirconium bromide $ZrBr_4$, crystalline white powder, and zirconium iodide ZrI_4 , yellowish-brown powder, are prepared by passing over heated zirconium or its carbide a stream of bromine vapour or hydrogen iodide respectively (Ber. 1904, 37, 1135; 1905, 38, 2611). The corresponding oxy-salts $ZrOBr_2 \cdot 8H_2O$ and $ZrOI_2 \cdot 8H_2O$ are produced by hydrolysis.

Zirconium carbide ZrC , hard metallic mass, scratching quartz but not ruby, is obtained by heating an intimate mixture of zirconia and carbon in the electric furnace (Moissan and Lengfeld, Compt. rend. 1896, 122, 651). A mixture of calcium carbonate, carbon, and zircon gives a similar result after extracting the fused mass with water and dilute hydrochloric acid. The carbide is also produced by heating native zirconia with carbon, using a current of 600 ampères (Wedekind, Ber. 1902, 35, 3929; Chem. Zeit. 1907, 31, 654). Zirconium carbide melts at 3400°-3500° Abs. (Friederich, Chem. Soc. Abstr. 1925, ii. 128, 374). It is an excellent conductor of electricity. A mixture of 90 parts with 10 parts of ruthenium made into filaments has been suggested for use in incandescent lamps. When heated in nitrogen the carbide furnishes zirconium nitride Zr_3N_4 . This nitride may also be obtained by heating the tetra-ammonia derivative of zirconium chloride $ZrCl_4 \cdot 4NH_3$ at 350° (Bruère and Chauvenet, Compt. rend. 1918, 167, 201). The nitride Zr_3N_4 is obtained by heating the metal in nitrogen at 1050°, D^{18}_4 0.75.

The extreme hardness of zirconium carbide renders it suitable as a polishing material and for cutting glass.

Zirconium silicide $ZrSi_2$, iron-grey rhombic crystals, sp.gr. 4.88 at 22°, is prepared by the aluminothermic process (200 parts aluminium, 250 parts sulphur, 180 parts sand, and 40 parts potassium zirconofluoride covered with a thin layer of magnesium as priming). It is not attacked by acids except hydrofluoric acid, and is only decomposed by caustic potash at moderately high temperatures (Compt. rend. 1906, 143, 224; v. Ber. 1902, 35, 3929). A colloidal variety of zirconium silicide has been observed (Zeitsch. Chem. Ind. Kolloide, 1910, 7, 249).

Zirconium silicate may be used in the preparation of opaque glazes and enamels in place of tin oxide.

Zirconium phosphate $ZrP_2O_7 \cdot 2H_2O$. Prepared by adding a solution of Na_2HPO_4 in 6N-hydrochloric acid to zirconium oxychloride in hydrochloric acid (Hevesy and Kimura, Zeitsch. angew. Chem. 1925, 38, 774). Zirconium phosphate is dissolved by hydrofluoric, oxalic, phosphoric, and conc. sulphuric acids (De Boer and van Arkel, Zeitsch. anorg. Chem. 1925, 144, 190; 148, 84).

Zirconium phosphite $Zr(PO_3)_2 \cdot H_2O$ is readily obtained by precipitation.

Zirconium hypophosphite $Zr(OPH_2O)_2 \cdot H_2O$ is obtained by adding hypophosphorous acid to a solution of zirconium nitrate until the precipitate has redissolved and then adding alcohol. It forms colourless, highly refracting crystals, which become deep violet on exposure to light (Häuser and Herzfeld, Zeitsch. anorg. Chem. 1913, 84, 92).

rhombic crystals from sulphuric acid solution. It is isomorphous with uranium sulphate $\text{U}(\text{SO}_4)_2 \cdot 4\text{H}_2\text{O}$, and with cerium sulphate (Fernandes, Atti R. Accad. Lincei, 1925, [vi.], 2, 182; Gazz. chim. Ital., 1925, 55, 290) differs considerably in its properties from the oxychloride. The zirconium present is not precipitated as oxalate by oxalic acid or its soluble salts, and the precipitation which occurs with the aqueous chloride is prevented by the addition to this solution of sulphuric acid or an alkali sulphate. In hydrochloric acid solutions of the chloride the zirconium ion passes to the cathode on electrolysis, but in solutions of the sulphate the zirconium passes to the anode in the complex anion $(\text{ZrOSO}_4 \cdot \text{SO}_4)^{2-}$ (v. Hauser, Zeitsch. anorg. Chem. 1905, 45, 185; 1907, 53, 74; 54, 190; J. pr. Chem. 1907, [ii.] 76, 363; Ruer, Zeitsch. anorg. Chem. 1904, 42, 87; 1905, 46, 449).

(2) *Basic sulphates* (i.) 4 : 3 *Basic sulphate* $\text{Zr}_4(\text{SO}_4)_3(\text{OH})_{10} \cdot 10\text{H}_2\text{O}$, microscopic birefringent needles, separates at 39.5° from a solution of 10.2 molecules of $\text{Zr}(\text{SO}_4)_2$ in 1000 molecules of water. When dried at 300° the anhydrous compound $4\text{ZrO}_2 \cdot 3\text{SO}_3$ is obtained (Ber. 1904, 37, 2024; Zeitsch. anorg. Chem. 1910, 67, 369; Hauser and Herzfeld, Zeitsch. anorg. Chem. 1919, 106, 1).

(ii.) 2 : 3-*Basic sulphate*

is obtained in a crystalline form by boiling concentrated solutions of zirconium sulphate; in cold water it gradually changes into the preceding basic salt.

(iii.) 5 : 2-*Basic sulphate* $5\text{ZrO}_2 \cdot 2\text{SO}_3 \cdot 14\text{H}_2\text{O}$ or $\text{Zr}_5\text{O}_8(\text{SO}_4)_2 \cdot 14\text{H}_2\text{O}$ is obtained by adding sulphuric acid or ammonium sulphate to the 5 : 4-basic chloride (Rodd, l.c.; cf. Rossiter and Sanders, J. Soc. Chem. Ind. 1921, 40, 70 T).

(3) *Acid sulphate* $\text{Zr}(\text{SO}_4)_2 \cdot \text{H}_2\text{SO}_4 \cdot 3\text{H}_2\text{O}$, monoclinal prisms or needles, is a very hygroscopic salt produced by adding strong sulphuric acid to an aqueous solution of zirconylsulphuric acid (Zeitsch. anorg. Chem. 1907, 54, 196).

(4) *Complex sulphates*. These are of two types $\text{Zr}_2\text{O}_3(\text{SO}_4)_2 \cdot x\text{H}_2\text{O}$ and $\text{Zr}(\text{SO}_4)_2 \cdot x\text{H}_2\text{O}$, where R is an alkali metal; the former are produced by adding an alkali sulphate to a solution of zirconium oxide in aqueous alkali disulphate and the latter by dissolving zirconium hydroxide in a boiling saturated solution of alkali disulphate (Ber. 1907, 40, 803, 810).

Combinations of normal zirconyl sulphate with alkali sulphates have been described by Chauvenet and Gueylard (Compt. rend. 1918, 167, 24; cf. Hauser and Herzfeld, l.c.).

Zirconium nitrate. Aqueous solutions of zirconium hydroxide in nitric acid yield on evaporation *basic nitrates* $\text{Zr}(\text{NO}_3)_2 \cdot 2\text{H}_2\text{O}$ and $\text{Zr}_2\text{O}_3(\text{NO}_3)_2 \cdot n\text{H}_2\text{O}$ (Chauvenet and Nicolle, Compt. rend. 1918, 166, 821).

Zirconium nitride, m.p. 2530° D 6-93, is prepared by heating the oxide with carbon in nitrogen at 1900° (Z. Physik. 1925, 21, 813).

Normal zirconyl citrate $(\text{ZrO})_2(\text{C}_6\text{H}_5\text{O}_7)_2$ may be prepared by adding a dilute solution of

acid to a freshly prepared solution of zirconyl chloride. If the zirconyl chloride is boiled before precipitation the basic compound

is formed (Venable and Lineberry, J. Amer. Chem. Soc. 1922, 44, 1708).

Zirconium oxalate is a basic salt $\text{ZrO}(\text{C}_2\text{O}_4)_2 \cdot \text{H}_2\text{O}$ or $4\text{H}_2\text{O}$, white powder, hydrolysed by water. By saturating aqueous oxalic acid with zirconium hydroxide an *acid oxalate* $\text{Zr}(\text{OH})(\text{C}_2\text{O}_4)_2 \cdot 7\text{H}_2\text{O}$ is obtained in large prisms. Double oxalates are produced by dissolving zirconium hydroxide in solutions of the alkali hydrogen oxalates (Mandl, Zeitsch. anorg. Chem. 1903, 37, 252; v. Venable and Baskerville, J. Amer. Chem. Soc. 1897, 19, 12).

Zirconium acetylacetonate

crystallises from an aqueous solution of zirconium nitrate and acetylacetone to which sodium carbonate is cautiously added; it is dehydrated by repeated crystallisation from absolute alcohol when it separates in needles.

Zirconium tetrachloride reacts with benzoylacetone in dry ether to form $(\text{CHAcBz})_2\text{ZrCl}_2$, m.p. 232°-231°, or in boiling benzene to form $(\text{CHAcBz})_2\text{ZrCl}_2$, m.p. 129° (Morgan and Bowden, Chem. Soc. J. 1924, 125, 1252; Dilthey, J. pr. Chem. 1925, ii. 111, 147).

Hafnium. *Cultum*. Associated with zirconium and found in many common zirconium minerals to the extent of from 1 to 30 p.c. of their zirconium content, especially the zircons and zirconium minerals like alvite, cyrtolith, naegeite, and malakon, is the element *hafnium*, discovered by G. von Hevesy and Cooter by using Moseley's method of X-ray spectroscopy. The zirconium extracted from alakon contains 21 p.c. of hafnium, and a specimen of cyrtolith from Rockport contained 10 p.c. hafnium. The methods of separating hafnium from zirconium are based partly on the different solubilities or vapour pressures of the corresponding compounds, partly on the difference in their basicity. The solubilities of the double fluorides $(\text{NH}_4)_2\text{RF}_6$, $(\text{NH}_4)_2\text{RF}_6$, and K_2RF_6 of zirconium and of hafnium have been determined by Hevesy, Christiansen, and Berglund (Zeitsch. anorg. Chem. 1925, 144, 69).

The most practical method of separation is the crystallisation of the double fluorides of potassium or ammonium. The mineral is melted with KFHF and the K_2ZrF_6 extracted with boiling water, in which this compound is soluble to the extent of 25 p.c. cent. On cooling down the greater part of the salt crystallises out. The zirconium double fluoride being less soluble (2.6 p.c. at 20°) than the hafnium double fluoride (nearly 3 p.c. at 20°), the latter accumulates in the mother liquor. Still more convenient is the crystallisation of the highly soluble $(\text{NH}_4)_2\text{ZrF}_6$, soluble at 20° to the extent of 26 p.c. The ammonium double fluoride of hafnium crystallises in beautiful prismatic (pseudo-hexagonal) crystals. The next suitable method of separation is the crystallisation of the ammonium zircon oxalate. A soluble zirconium salt, like the stilphate, is precipitated with ammonia, the hydroxide dissolved in an excess of oxalic acid and neutralised with ammonia. By crystallising the oxalate formed, hafnium accumulates in the mother liquor.

G. Hevesy and V. T. Jantzen have given detailed accounts (*Chem. News*, 1923, 127, 353, see also De Boer and van Arkel, *Zeitsch. anorg. Chem.* 1924, 141, 284) of the preparation of ammonium zirconium fluoride and ammonium hafnium fluoride from alvite, and of the separation of hafnium from this mineral by the double fluoride method, employing the ammonium double fluorides (*Abstracts*, 1923, ii, 570). For the separation of zirconium and hafnium by fusing the ores with hydrofluoric acid and potassium fluoride, see also Fr. Pats. 568971, 569016; *Chem. Soc. Abstr.* 1925, 128, ii, 62, 63).

Less satisfactory is the result of the crystallisation of the complex sulphate, like the ammonium salt of zirconium and sulphuric acid. The hafnium concentrates here also in the mother liquor (see also Marquis and Urbain, *Compt. rend.* 1925, 180, 1377).

Hafnium phosphate $\text{HfH}_2\text{P}_2\text{O}_7$ is less soluble in hydrochloric acid than zirconium phosphate, and a separation of the two may be carried out in concentrated acid (von Hevesy and Kimur, *Zeitsch. angew. Chem.* 1925, 38, 774; *J. Amer. Chem. Soc.* 47, 2540).

To purify zirconium from iron and other impurities it is often converted into the oxychloride. By repeatedly crystallising this compound from hydrochloric acid pure zirconium is retained. Hafnium oxychloride is less soluble than zirconium oxychloride; thus while purifying zirconium from iron, its hafnium content is raised at the same time. For example, starting from 100 grs. ZrOCl_2 containing 1 p.c. hafnium, the 30 grs. oxychloride residue obtained after 10 successive crystallisations contained a little over 2 p.c. hafnium.

Hafnium is more basic than zirconium, and accordingly when precipitating a solution of a zirconium salt with ammonia the first precipitate contains less hafnium than the successive ones.

For example, when precipitating one half of an oxychloride solution containing 1 p.c. hafnium with dilute ammonia, the precipitate contains only 0.8 p.c., whilst the hafnium content of the solution is increased to 1.2 p.c. This difference can be somewhat increased by the presence of large amounts of ammonium chloride in the solution. By boiling a solution of zirconium and hafnium with sodium thiosulphate, zirconium being more strongly hydrolysed, the first precipitate contains a larger amount of zirconium than the successive ones. From a solution of zirconium sulphate, diluted about 1:40, a basic zirconium compound precipitates on standing a few days at 39.5°. Also with this process, like many similar ones, the precipitate contains slightly more zirconium than the solution.

The difference in the basicity is also shown on heating the neutral sulphate of zirconium or hafnium; whereas the first mentioned compound begins to decompose above 400°, the decomposition temperature of $\text{Hf(SO}_4)_2$ lies about 100° higher.

On dissolving the oxychloride in alcohol and precipitating with ether a higher basic compound $\text{Zr}_2\text{O}_3\text{Cl}_2 \cdot 5\text{H}_2\text{O}$ is formed, which is found to be less soluble than the corresponding hafnium compound. This difference in the solubilities was repeatedly used by V. T. Jantzen

and von Hevesy to purify concentrated hafnium preparations from zirconium.

In some cases, including the phosphate, salicylate, the hafnium compounds were found to be less soluble than the corresponding zirconium compounds.

Like zirconium tetrachloride, hafnium tetrachloride also volatilises appreciably at about 250°, and the first distillate contains somewhat more zirconium than hafnium.

Though hafnium is to be placed in the periodic table between zirconium and thorium where formerly cerium was placed, its chemical properties are not intermediate between those of zirconium and thorium, but much nearer to the former element. It is of interest to note that in several cases the solubility of the hafnium compound is greater than the solubility of the corresponding zirconium compound and thorium compound. Thus the solubility of the hafnium double fluoride is much greater than that of the thorium double fluoride and somewhat greater than the solubility of the zirconium double fluoride (G. von Hevesy, *Brit. Assoc. Reports, Liverpool Meeting*, 1923). A preliminary determination employing hafnium containing from 5 to 6 p.c. of zirconium indicated that the atomic weight of hafnium is between 178.4 and 180.2.

The atomic weights of the zirconium of the rare earth fractions of a number of zirconium minerals have been determined. The zirconium fractions of the different minerals (purified through the oxychloride, $\text{ZrOCl}_2 \cdot 8\text{H}_2\text{O}$, which does not cause removal of hafnium) gave atomic weights varying from 90.3 to 95.0, as determined from the conversion of sulphate into oxide. The higher atomic weights corresponding with a higher hafnium content, were obtained with minerals of higher rare earth (yttrium metals, atomic weight 96-93) content (E. Urbain and G. Urbain, *Compt. rend.* 1924, 178, 268; *Chem. Soc. Abstr.* 1924, 126, ii, 194).

The density of hafnium dioxide at 20° is 9.67, while that of zirconium dioxide is 5.73. This difference may be used in determining the percentage of hafnium dioxide in zirconia (Hevesy and Berglund, *Chem. Soc. Trans.* 1924, 125, 2372).

ZIRKELITE. Zirconate, titanate, and thorate of calcium, iron, &c.

crystallised in the rhombohedral system. Analyses show ZrO_2 , 30.73-52.80, ThO_2 , 0.23-20.44, UO_2 , 1.4-14 replacing thoria, Ce_2O_3 , &c. up to 3.61, Y_2O_3 up to 1.08 p.c. The mineral is black or brownish-black, opaque, and with a resinous to sub-metallic lustre; sp.gr. 4.70-5.22, H. 5½; slowly decomposed by hydrochloric acid, but readily by hydrofluoric acid. Crystals are small, and their form is usually obscured by twinning. Crystals of octahedral habit are found with baddeleyite in the rock jacupirangite (a magnetite-pyroxenite) at the Jacupiranga iron mine in São Paulo, Brazil. Grains and crystals are found in the gem-gravels at several places in Sabaragamuwa province, Ceylon. L. J. S.

ZIRKITE or BADDELEYITE.

Zirkite is an impure zirconium dioxide containing silica, iron, and titanium as the chief

Properties. It is not suitable as a refractory, since its melting-point lies between 1200° and 2000°, whilst that of zirconium oxide is 2950°-3000°. The mineral may be converted into a substance sufficiently refractory for most purposes by heating a mixture of the ore with coke in an arc furnace, the amount of carbon being such that it will combine with the silicon alone. Such treatment removes 90-95 p.c. of the silicon; if, however, the amount of coke is in excess of that stated, the removal of the silicon is less complete, owing to the formation of stable double carbides of zirconium and silicon. When the silicon has been removed the iron is removed by treatment with chlorine. Zirconium carbide is exceedingly refractory, being infusible in a 40-50 kw. arc, but its use is restricted as it is oxidised at high temperatures (Thompson, J. Phys. Chem. 1922, 26, 812, J. Soc. Chem. Ind.

In order to prepare zirconium oxide, zirkite is digested at 275°-310°C. with concentrated sulphuric acid (sp.gr. 1.84) in the proportion of 2 parts of acid to 1 part of ... About 57 p.c. of the zirconia content of the ore passes into solution; the remainder is combined with silica and insoluble under these conditions. The product is diluted with about 20 times its volume of water and the insoluble portion filtered off. The solution of the basic sulphate is then treated with calcium carbonate or chloride, or a mixture of carbonate and chloride, in such a quantity as is necessary to reduce the sulphuric acid content to a value equal to one-half the zirconium dioxide content. The calcium sulphate is filtered off, the filtrate considerably diluted (about 50 times), and the precipitate filtered off, washed and strongly heated. The result is not so good with calcium chloride alone as with calcium carbonate, but the product in the former case is whiter and more granular (Bain and Gollop, Canad. Chem. and Met. 1922, 7, 35; J. Soc. Chem. Ind. 1923, 42, 351 A.). For methods of improving the refractory qualities of zirkite by eliminating the associated impurities, the chief of which are silicon, iron, and titanium. The melting-point of the raw ore varies from 1200°-2000°, while that of the pure oxide is 2950°-3000°. The method for purification found most satisfactory is based on the fact that zirconium carbide is stable at temperatures above the decomposition point of silicon carbide (J. G. Thompson, J. Phys. Chem. 1922, 26, 812).

A rock-forming mineral of the

epidote group, consisting of basic calcium aluminium silicate $2\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot 2\text{H}_2\text{O} \cdot \text{SiO}_2$, or $\text{Ca}_2(\text{AlOH})_4(\text{SiO}_3)_2$, crystallised in the orthorhombic system. Crystals are prismatic in habit and have a perfect cleavage parallel to the brachypinacoid; but the mineral is more often found as columnar or compact granular masses of a dull greyish colour. Sp.gr. 3.3, H. 6; decomposed by hydrochloric acid after being previously heated. It occurs as a constituent of crystalline schists. An interesting variety, known as *thulite*, is found as rose-pink granular masses at Lerviken near Trondhjem, and intermixed with sky-blue vesuvianite ('cyprius') at Souland, Telemark, Norway. This polishes well and is occasionally used as an ornamental stone. A rock also sometimes used for small ornaments in the prettily coloured eclogite from Sau Alp in Carinthia, and the Fichtel in Bavaria; this consists of emerald-green blende ('smaragdite'), reddish garnet, and bluish-grey zoisite. L. J. S.

ZOOMARIC ACID ($\text{C}_{18}\text{H}_{30}\text{O}_2$), an acid discovered by Bull in cod liver oil, and found in the oils and fats of most marine animals.

ZORGITE. Selenide of lead and copper ($\text{Pb,Cu}_2\text{Se}$), containing Se 29-34 p.c. It is a massive granular mineral with a lead-grey colour and metallic lustre. Sp.gr. 7-7.5, H. 2½. It is found together with other selenides at Zorge and several other localities in the Harz, and at Cacheuta in Mendoza, Argentina. L. J. S.

ZYCLOFORM *p*-Aminobenzoic isobutyl ester.

ZYGADENINE. A crystalline alkaloid ($\text{C}_{13}\text{H}_{15}\text{NO}_3$) found in the leaves of *zygadenus intermedius*. Shining needles from benzene; rhombic crystals from alcohol, m.p. 200°-201°. Very soluble in chloroform, sparingly soluble in ether. Specific rotation in chloroform -48.2°. An acid solution precipitates Mayer's reagent, gives a crystalline chloroaurate. With conc. sulphuric acid, an orange colour changing to cherry-red. In physiological action resembles veratrine (Henry, Hepner and Loy, J. Amer. Chem. Soc. 1913, 35, 258).

ZYMASE *v.* FERMENTATION.

ZYMIN *v.* SYNTHETIC DRUGS.

ZYMURGY. A term used to denote that section of applied chemistry which treats of the scientific principles of those arts in which fermentation is employed—e.g. preparation of yeast, vinegar, wine, beer, alcohol.

 2-p-Dimethylaminostyrylpyridene methiodide, v. 229r
 2-Dimethylaminotoluene, 5-amino-, vii. 158r
 4-Dimethylaminotoluene, 3-amino-, vii. 159r
 5-Dimethylaminotoluene, 2-amino-, vii. 157r
 3 : 5-Dimethylaminotoluene, 2 : 4-dinitro-, and 2 : 4 : 6-trinitro-, vii. 159r
 4-Dimethylaminotoluene, 5-nitro-3-acetylamino- and 6-nitro-3-acetylamino-, vii. 159r
 5-Dimethylaminouracil, iv. 321r
 4 : 6-Dimethylamino-*m*-xylene, vii. 550r
 4-Dimethylamino-*m*-xylene, 6-nitro-, vii. 548r
 Dimethylaniline, ii. 528r
 —, *p*-nitroso, iv. 613r
 o-Dimethylantracene, iv. 338r
 2 : 6-Dimethylantracene, iv. 341r
 2 : 7-Dimethylantracene, iv. 341r
m-Dimethylantracene, iv. 329r
 Dimethylantracene, chloro- and hydroxy-, derivatives of, iv. 342r
 —, nitro-derivatives of, iv. 342r
 Dimethylanthrachryson, iv. 343r
m-Dimethylanthracylene, iv. 340r
p-Dimethylanthracylene, iv. 341r
 Dimethylantracisavic acid, iv. 343r
 Dimethylantragallol, iv. 343r
 2 : 6-Dimethylantraquinone, iv. 341r, 343r
o- (or 2 : 3) Dimethylantraquinone, iv. 339r
m-Dimethylantraquinone, iv. 340r
p-Dimethylantraquinone, iv. 340r
 Dimethylantraquin and its carboxylic acid, iv. 343r
 2 : 6-Dimethylantraquinone, 1 : 5-dihydroxy-, 3 : 4-dihydroxy-, and 3 : 6-dihydroxy-, iv. 343r
 Dimethylanthracene, iv. 342r
 Dimethylanthracene, iv. 343r
 Dimethylbenzene, amino-, vii. 540r
 Dimethylbenzenes, vii. 515r-563r
 $\alpha\beta$ -Dimethylbutyric acid, ii. 20r
 Dimethylchloramine, iv. 520r
 Dimethyldiaminotoluphenasine, i. 443r
 4-Dimethyl-4 : 6-diamino-*m*-xylene and derivatives, vii. 550r
o-Dimethyl-4 : 6-diamino-*m*-xylene and derivatives, vii. 550r
 2 : 2'-Dimethyl-1 : 1-dianthraquinonyl, iv. 350r
 9 : 10-Dimethyl-9 : 10-dihydroxydihydroanthracene, iv. 347r
 Dimethyldilituric acid and its chloro-derivative, ii. 528r
 Dimethylene dimethyl, and diethyl diamines, iv. 326r
 Dimethyl ether, iv. 314r
 Dimethylethylacetic acid, ii. 20r
 Dimethylethyl-carbinol, vi. 618r
 — chloral, vi. 619r
 Dimethylethylenediamine, i. 718r
 Dimethylethylene glycol, i. 718r
o-Dimethylethylene oxide, i. 718r
 Dimethylglyoxime, ii. 528r; iii. 720r
as-Dimethyl hydrazine, and *sym*dimethyl hydrazine, iv. 324r
 Dimethyl ketene, iii. 702r
 — ketone, i. 34r
 Dimethylmalonic acid and dimethylmalonamide, iii. 427r
 2 : 6-, 2 : 7-, and 2 : 3-Dimethylnaphthalenes, iv. 359r
 1 : 4-, and 1 : 6-Dimethylnaphthalenes, iv. 358r
 Dimethylnitramine, iv. 320r
 Dimethyl oxalic acid, iii. 573r
 Dimethylphenylpyrazolone mercury sulfamate, vi. 625r
 Dimethylpiperazine tartrate, vi. 633r
aa-Dimethylpropionic acid, ii. 20r; vii. 390r
 Dimethyl pyridines, mono-, di-, and tricarboxylic acids of, i. 634r
 Dimethylpyrrole, i. 630r
 2 : 4-Dimethylquinoline, v. 546r
 Dimethylrhen and derivatives, iv. 363r
 Dimethyl-succinonitrile, i. 717r
 — sulphate, iv. 315r
 — *o*-toluidine and its derivatives, vii. 136r
 — *m*-toluidine and its derivatives, vii. 142r
 — *p*-toluidine and its derivatives, vii. 150r
 — *o*-toluidine (?) sulphonic acid, vii. 153r
 2 : 6-Dimethyltolylenediamine, 3 : 5-dinitro-, vii. 158r
 1 : 3-Dimethylxanthine, vi. 634r
 3 : 7-Dimethylxanthine, vi. 634r
 Dimethylxanthines, employment of as drugs, vi. 634r
 Dimethyl-*o*-4-xylidine, vii. 543r
 — *m*-2-xylidine, vii. 545r
 — *p*-2-xylidine, vii. 552r
 — *o*-3-xylidine, and its alkylamino and arylamino-derivatives, vii. 542r
 — *m*-4-xylidine and its 5-bromo-derivative, vii. 547r
 — *m*-5-xylidine and its nitroso-derivative, vii. 549r
 Dinaphthadiquinones, v. 578r
 Dinaphthanthraquinone, v. 583r
 Dinaphthanthratricinone, v. 584r
 Dinaphthazine, i. 440r
 2 : 6-Di-*a*-naphthoanthraquinone, iv. 341r
 Di-*a*-naphthylanthracene, iv. 340r
 2 : 2'-Dinaphthylcarbamide, 5 : 5'-dihydroxy-7 : 7'-disulphonic acid, ii. 526r
aa-Dinaphthyl carbonate and sulphite, iv. 467r
 $\beta\beta$ -Dinaphthyl carbonate and sulphite, iv. 477r
peri-Dinaphthylene and its derivatives, v. 196r
 Dinaphthylmethenaphthalene, quinonoid-*peri*- and benzenoid-*peri*-, v. 656r
 $\beta\beta$ -Dinaphthyl ether, iv. 477r
 Dinicotinic acid, i. 633r

- Dinitrophenol black, vi. 496f
 Diocetylmalonic acid, ii. 530f
 Dioform, ii. 530f
 Diogen, ii. 530f
 Diogenal, ii. 530f; vi. 620r
 Dionine, ii. 530f; vi. 622f
 Diopside, ii. 530f
 Diopside, ii. 530f
 Diorite, ii. 530r
 Diormellinic acid, iv. 106r
 Dioscorine, ii. 530r
 2 : 4-Dioximinobenzo-1 : 2 : 3 : 4-diquinone, v. 606f
β-Dioximinobutane, ii. 528r
 Dioxine, v. 607f
 Dioxodisiloxane, vi. 88r
 Dioxorea, ii. 531f
 1 : 8-Dioxyanthraquinone, vi. 643f
 Dioxyanthraquinone-quinoline and its sodium bisulphite compound, i. 619f
 Dioxyethylene, ii. 681f
 Dioxygen, ii. 531f, 539f
 2 : 6-Dioxypurine, vii. 504r
 Dipentenes, vi. 732r
 Diphenal, ii. 531f
 Diphenazine, i. 439r
o-Diphenetidine, ii. 533r
 Diphenic acid, v. 163r
 ———, *m*-diamino-, v. 164f
 Diphenol, diaminohydroxy-, ii. 531f
o-Diphenol, tetrabromo-, employment and action of as a drug, vi. 630r
 Diphenol-*γ*-pyrone, vii. 511f
 Diphenquinone, v. 585f
 ———, tetrahydroxy-, and tetramethoxy-, v. 546f; tetraethoxy-, v. 586r
 Diphenyl, ii. 531f
 Diphenylamine, ii. 533r
 ———, alkyl, amino, and other derivatives, ii. 534r
 ———, *p*-amino-, i. 198f
 ———, 2 : 4-dinitro-4'-hydroxy-, ii. 529r
 ———, hexanitro-, i. 433f; iii. 87f
 ———, tests for, ii. 534r
 3 : 5-Diphenylaminotoluene, 2 : 4-dinitro-, and 2 : 4 : 6-trinitro-, vii. 159r
 Diphenylanthrone and its dihydroxy derivative, iv. 349f
 Diphenylboric acid, i. 650f
 Diphenylcarbinol, vii. 183f
 ———, hexabromodihydroxy-, vi. 630r
 Diphenyl catechins G, i. 491r
 ———, chrysoine G and RR, i. 491r
 Diphenylcitronine G, i. 490r
 Diphenyl, derivatives of, v. 163r
 ———, 4 : 4'-diamino-2 : 2'-dicarboxylic acid, v. 164f
 ———, 2 : 2'-dicarboxylic acid, v. 163r
 9 : 10-Diphenyl-9 : 10-dihydroxydihydroanthracene, iv. 348r
 Diphenyl-dimethylolid, ii. 535f
 3 : 3'-Diphenyldiquinone, v. 577r
 3 : 3'-Diphenylene-ethylene, v. 157f
 Diphenylene ketone oxide, vii. 51N
o-Diphenylene methane, iii. 225f
 1 : 4-Diphenyl-3 : 5-enolanilodihydrotriazole, iv. 606f
sym-Diphenylethylene, preparation of, vi. 402r
 Diphenylhydrazine, iii. 535r
 Diphenylimide, *β*-amidothio-, i. 583f
 Diphenylketone, iii. 703f
 Diphenylketone, iii. 713r
 Diphenylmethane, ii. 535r; vii. 183f
 Diphenylmethanedimethylhydrazine, ii. 27f
 Diphenylmethane, properties, reactions and derivatives of, ii. 536f
 Diphenyl piperazine, v. 307f^o
 ———, quinones derived from, 4 : 4'-diphenyl quinones and derivatives of, v. 585f
 Diphenylrosanilines, vii. 198r
 Diphenyl tetracoside, v. 35f
 Dir *j*-*m*-toluidine and its derivatives, vii.
 ———, violuric acid, molecular phase change in connection with compounds of, vi. 332f
 ———, ———, spectroscopic evidence on formula of, vi. 329f
 Dipecolinic acid, i. 633f
 Diploal, ii. 536r; vi. 617f
 Dippel's oil, i. 627r
 Dipropasin, ii. 536r
 Dipropylamine, v. 455r
 Diisopropylamine, v. 456r
 Dipropylbarbituric acid, vi. 620r
 Dipropyl ketones, i. 721r
 Diprotocatechuic acid, vi. 658r
 Dipyridine, i. 631f
m-Dipyridyl, i. 631r
 Diquinine carbonate, ii. 267r
 ———, carbonic ester, vi. 623f
 Di-*β*-resorcylic acid, vi. 658r
 Disaccharides, ii. 45r
 Disalicylide, vi. 24r
 Disalol, ii. 536r
 Disazo-compounds, i. 471r; ii. 537f
 Disilane, vi. 89r
 Disilicohydric pentabromide, vi. 93r
 Disilicon hexabromide, vi. 93r
 ———, hexachloride, vi. 91r
 ———, hexaiodide, vi. 93r
 Disinfectants, ii. 538f-555r; vi. 624f
 ———, acids, ii. 543r
 ———, aromatic acids, ii. 550f
 ———, essential oils and camphors, ii. 552f
 ———, germicidal power of various in terms of carbolic acid, ii. 555r
 ———, hydrocarbons, ii. 552f
 ———, influence of linked benzene derivatives on, ii. 551r

 Propane, *αα*-heptachloro-, ii. 73l
 —, *α*-hydroxy-, v. 452r
 —, *β*-hydroxy-, v. 453l
 —, *α*-hydroxy-*β*-methyl-, i. 711l
 —, 2-ol, 1; 3 diiodo-, vi. 628l
 Propanolone, i. 33r
 Propanonic acid, iii. 728r
 Propargyl alcohol, v. 448l
 Propargylic acid, v. 448l
 Propenyl alcohol, iii. 430l
 Propiolic acid, v. 448l
 —, alcohol, v. 448l
 —, aldehyde, and propiolamide, v. 448l
 —, compounds and alkylpropiolic acids, v. 447r
 Propion, v. 448r
 Propionic acid, v. 448r
 —, *β*-aceto-, i. 38l
 —, *α*-amino-, v. 458l
 —, *α*- and *β*-amino-, salts and derivatives of, i. 89l
 —, *α*-amino-*β*-hydroxy-, vi. 67l
 —, *β*-amino-*α*-hydroxy-, vi. 68l
 4-(or 5) Propionic acid, *l*-*α*-amino-*β*-glyoxalino-, iii. 518l
 Propionic acid, antiseptic properties of, ii. 54l
 —, *β*-disulphido-*α*-amino, ii. 477r; v. 458
 —, *α*-hydroxy-, iv. 5l
 —, *β*-hydroxy-*α*-amino-, v. 458l
 —, *β*-*para*-hydroxyphenyl-*α*-amino-, 458l
 —, *β*-iminazolo-*α*-amino-, iii. 518l
 —, *β*-phenyl-*α*-amino-, v. 458l
 Propionitrile, ii. 659r
 Propionyl-*p*-phenetidine, vi. 616l
 Propolis, propolis resin, wax, and balsam, v. 449l
 Propenal, v. 449l; vi. 620r
 Propenote, v. 449l
 Propyl, v. 449l
 —, alcohol, v. 452r
*iso*Propyl alcohol, v. 453l
 —, *α*-dichloro-, carbamic acid esters of, vi. 620l
 Propyl alcohol, effect of addition of salt on its solubility in water, vi. 281r
*iso*Propyl alcohol, trichloro-, iii. 685r; vi. 619l
 Propylamine, v. 455l
*iso*Propylamines, v. 455r, 456l
 Propyl *p*-aminobenzoate, vi. 637l
 Propylbenzenes, normal and *iso*-, ii. 433l
 Propyl-, and *isopropyl*benzenes, *o*- and *p*-amino-, ii. 434r
 Propyl bromide, v. 449r
*iso*Propyl bromide, v. 450l
 Propyl butyrates, i. 721l
 Propyl isobutyrate, i. 721r
*iso*Propyl carbimide, v. 454l
 Propyl carbinol, i. 710r
iso-Propyl carbinol, i. 711l
 Propyl carbylamine and *isopropyl* carbylamine, v. 454l
 —, chloride, and *isopropyl* chloride, v. 451l
 —, chlorosulphinate and propyl sulphuric acid, v. 454r
*iso*Propyl isocyanate, v. 454l
 Propyl cyanide and *iso*-propyl cyanide, v. 454l
 —, isocyanide and *isopropyl* isocyanide, v. 454l
 Propylene, v. 456l
 —, diamino, v. 456l
 —, dibromide, v. 450l
 —, dichloride, v. 451l
 —, diiodide, v. 452l
 Propyleneglycol, v. 453l
n-Propylene glycol, v. 453r
 1-*iso*Propyl-4-ethanalbenzene, vii. 320r
 Propyl, higher chlorinated derivatives of, v. 451r
 —, hydrogen sulphate, v. 454r
 Propylidene dibromide, v. 450l
 —, dichloride, v. 451l

- Propyl iodide, and isopropyl iodide, v. 452f
 — mercaptan and isopropyl mercaptan, 454r
 β -isoPropyl- ϵ -methyl- ϵ -caprolactone, iv. 19f
 Propyl mustard oil, v. 454f
 isoPropyl mustard oil, v. 454r
 Propyl nitrate and isopropyl nitrate, v. 455f
 — nitrite and isopropyl nitrite, v. 455f
 — propionate, v. 449f
 isoPropylsuccinic acid, v. 303r
 Propyl sulphate and isopropyl sulphuric acid, 455f
 — sulphide and isopropyl sulphide, v. 454r
 n-Propyl tartrate, rotation dispersion of at different temperatures, v. 358r
 Propyl thiocarbimide, v. 454f
 isoPropyl thiocarbimide, v. 454r
 Propyl thiocyanate, isopropyl thiocyanate, and propyl isothiocyanate, v. 454f
 isoPropyl isothiocyanate, v. 454r
 Propylveronal, N-dibromo-, vi. 620r
 Protopogenin, iii. 416f
 Protactinium, v. 457r
 Protalbic acid, v. 457r
 Protamines, v. 463r
 Protan, v. 457r
 Protargol, vi. 133f, 626r
 Proteans or metaproteins, v. 461r
 Proteases, iii. 139r
 Protein, Bence-Jones, i. 626f
 Proteinchromogen, vii. 222r
 Protein, Dr. Reigel's milk, ii. 94f
 —, endogenous metabolism of in body, vi. 285r
 —, exogenous metabolism of, vii. 286f
 Proteins, v. 457r-470f
 —, biological reactions of, v. 467r
 —, chemical constants of, v. 467f
 —, chief natural, vegetable and animal, v. 46f
 —, — physical properties of, colloidal nature of, v. 462f
 —, classification of, the simple proteins, v. 46f
 —, coagulated, v. 464r
 —, colour reactions of, v. 461r
 —, conjugated, v. 464f, 468f
 —, crystallisation of, and other physical properties of, v. 463f
 —, derived, v. 464r
 —, —, and the hydrolysis of by enzymes, v. 469f
 —, identification of, and physical constants of, v. 466r
 Protein silver, vi. 626r
 Proteins, monoaminocarboxylic acids, dicarboxylic acids, diaminomono-carboxylic acids, and heterocyclic compounds isolated as hydrolysis products of, v. 458f
 —, percentage yields of the hydrolysis products of certain typical, v. 460
 —, precipitation reactions of, v. 460r, 467r
 —, quantitative estimation of hydrolysis products of, v. 458r
 —, reactions of, v. 460f
 —, separation and identification of naturally and separation of from one another, v. 468f
 —, solubility of, and the salting out of from solutions, v. 462r
 Protoal, ii. 547r
 Protoceas, v. 464r
 Proteus vulgare in soils, vi. 251r
 Protocatechuic acid, v. 470f
 Protocourina and protocourarine, ii. 435r
 Proton, v. 471r
 Protopine, ii. 396f; iv. 719f; v. 471r
 Protocol, vi. 617r
 Protocol, v. 472f
 Protopetratridine, ii. 148r
 Protopetratrine, ii. 148r
 Pronitrite, v. 472f; vi. 109f
 Prunasin, iii. 414f
 Prunasin, iii. 408r
 Prune, pure, iv. 737r
 Prunetin, and prunetol, their acetyl and other derivatives, v. 472f
 Prunicyanin and its chloride, i. 342r
 Prunitrin, iii. 414f
 Prussiate black, v. 300f
 Prussian blue, ii. 437r
 Prussic acid, see also Hydrogen cyanide.
 —, —, ii. 463r
 Przibramite, ii. 450.
 Pseudoaconine, i. 68r
 Pseudoaconitine, i. 66f, 68r
 Pseudohyoscyamine, vii. 221r
 Pseudomonas radicola, vi. 270r
 Pseudopapaverine, iv. 718r
 Pseudotropine, vii. 222f
 Pseudotropine, benzoyl-, vii. 221r
 Psilomelane, iv. 215f; v. 472r
 Psittacinite, v. 472r; vii. 293r
 Psychotrine, iii. 658r
 —, o-methyl ether, iii. 659r
 Pterocarpin and homopterocarpin, vi. 32f and r
 Ptomaines, and ptomaine poisoning, v. 479r
 Ptyalin, ii. 503f
 Puce, benzidine, i. 457r
 —, tolidine, i. 457r
 Pucherite, v. 473f; vi. 401r; vii. 293r
 Pulas, i. 700r
 Pulegone, ii. 8r; iii. 722r, 723r; vi. 747r
 Pulmoform, vi. 631r, 632f
 Pulque, i. 88f
 Pulvis algarothi, i. 113r
 Pumice or pumice stone, v. 473f
 Pumpkin, v. 473r
 Purgatol or purgatin, vi. 642r; vi. 643f
 Purgen, v. 474f; vi. 643f
 Purging nut tree oil, v. 474f
 Purglets, vi. 643f
 Purgolade, vi. 643f
 Purine, 6-amino-, and its derivatives, i. 76f, 727r
 — derivatives, employment of as drugs, vi. 633r
 —, 1 : 7-dimethyl-2 : 6-dioxy-, v. 78r
 —, 6-dioxy, i. 728f
 —, 6-oxy-, i. 727r
 Purines, v. 474f
 —, naturally occurring, v. 476f
 —, relation between structure and physical properties of, and physiological action of, v. 475f
 —, salts and derivatives of, v. 475r
 Purine, 2 : 6 : 8-trioxy-, vii. 279r
 Puriri, vii. 325r
 Purple, cotton, 5B, i. 485f
 —, ethyl, 6B, vii. 196f
 —, Heesman, N, i. 489r, brilliant, 490f
 — lakes, iv. 21r
 — of the ancients, Tyrian and Byzantium, ii. 588f; iii. 623r; v. 292f, 476f; vii. 249r, 314r
 — of Cassius, iii. 460f; v. 294r
 —, pigment A, i. 457f
 —, spirit, or regina spirit purple, vii. 199f
 Purples, regina, v. 666r; vii. 198r
 Purple, Thionol 2B and Thiogen, vi. 505r
 — Tyrian, ii. 588f; iii. 623r; v. 292f, 476f; vii. 249r, 314r
 Purpuric acid, iv. 397r
 iso-, and metaPurpuric acids, v. 477r
 Purpuric acid, salts of, iv. 399f
 Purpurin, i. 133f
 iso-Purpurin, i. 132f
 pseudoPurpurin, iv. 177r
 Purpurine, brilliant, i. 485r
 Purpurin, 3-chloro-, i. 133r
 — 3 : 8-disulphonic acid, i. 133r
 —, presence of in munjeet, iv. 397r
 Purpurogallin, v. 478f
 — derivatives of, v. 478r

- Purpurogallin, dyeing properties of, v. 479r
 Purpuroxanthin, i. 136r, 133r; iv. 178l
 — carboxylic acid, iv. 178r, 397r
 Purpuroxanthin, dichloro-, i. 133r
 Purree, piuri, or purree Arabica, iii. 599l; v. 42l, 300l
 Purrenone or purrone, iii. 599r
 Putrefaction, iii. 167r
 — bases, v. 479r
 — containing a carboxyl group, v. 480r
 — definition of term, v. 480l
 Putrescine, i. 717r
 — sources of, v. 480l
 Putrine, v. 481l
 Putty powder, v. 418r; vii. 59r
 Puzzolana or puzzuolana, vii. 226l
 Pyknometer, modified forms of Sprengel by Perkin and by Davis and Pratt, vi. 300l
 Pyknometers, Sprengel, and other forms of, vi. 299r
 Pyracetosalyl, v. 481r
 Pyramidone, i. 185r; vi. 616r
 isoPyramidone, v. 489r
 Pyramidone, detection of in antipyrine, v. 481r
 — estimation of, salts of, and reactions of, v. 488l
 —, salicylate, vi. 616r
 γ -Pyran or benzopyranol group, v. 481
 Pyranthrene, iii. 594l
 Pyrantimonite, iii. 702l
 Pyrantin, v. 482r; vi. 615r, 616l
 Pyrarгыrite, v. 482r; vi. 109l
 Pyrazine, i. 437l
 Pyrazole, v. 482r
 —, synthesis of alkyl derivatives of, v. 483l
 Pyrazolidines, v. 484l
 Pyrazolidone, v. 484l
 Pyrazoline, and its hydrochloride, platunichloride, and picrate, v. 484l
 Pyrazolone, v. 481r
 3-Pyrazolone, v. 484r
 Pyrazolone colouring matters, v. 489r
 5-Pyrazolone, 1-phenyl-2:3-dimethyl-, v. 486l
 —, literature of, v. 486r
 —, and 1-phenyl-2-methyl-5-pyrazolone, and 1-phenyl-3-methyl-5-pyrazolone, v. 485l
 Pyrazolones, 1-aryl-3-, 5-halogen methyl-2-, and 4-dialkyl-3-pyrazolone, v. 484r
 —, general preparation of, i. 32r
 —, sulpho- and other derivatives of, v. 486l
 Pyrene, v. 490r
 — ketone, iii. 728l
 — quinone, v. 584r
 Pyrethrum, employment of as a plant-spray, v. 321l and r
 — root, v. 491l
 Pyretol or pyrethron, v. 491l
 Pyrex glass, v. 491r
 Pyricit, ii. 543l
 Pyridine, i. 630r
 —, amino-, i. 632l
 —, antiseptic properties of, ii. 553r
 Pyridinecarboxylic acids and hydroxycarboxylic acids, i. 632r
 Pyridine, colouring matters derived from, i. 635r
 —, derivatives of, and some physical constants of, v. 491r
 —, dicarboxylic acids, i. 632r
 —, general preparation of, i. 32r
 —, halogen derivatives of, i. 633l
